Later the district formed the northern division of Mercia, and in 848 the Mercian witenagemot assembled at Repton. In the 9th century the district suffered frequently from the ravages of the Danes, who in 874 wintered at Repton and destroyed its famous monastery. Derby under Guthrum was one of the five Danish burghs, but in 918 was recovered by Aethelflaed. In 924 Edward the Elder fortified Bakewell, and in 941-942 Edmund regained Derby from the Danes. Saxon barrows are numerous in Wirksworth hundred and the Bakewell district, among them being White-low near Winstan and Bower's-low near Tissington. There are Saxon cemeteries at Stapenhill and Foremark Hall.

Derbyshire probably originated as a shire in the time of Aethelstan, but for long it maintained a close connection with Nottinghamshire, and Domesday gives a list of customs affecting the two counties alike. The two shire-courts sat together for the Domesday inquest, and the counties were under one sheriff until the time of Elizabeth. The villages of Appleby, Oakthorpe, Domesbury, Stretton-en-le-Feld, Wilsley, Chilcote and Measham were reckoned as part of Derbyshire in 1086, although separated from it by the Leicestershire parishes of Over and Nether

Seat Early divisions of the county were known as wapentakes, five being mentioned in Domesday while 13th century documents mention seven corresponding with the six present hundreds, except that Repton and Gresley were then reckoned as separate divisions. In the 14th century the divisions were described as hundreds, and Wirksworth alone retained the designation wapenake until modern times. Ecclesiastically the county constituted an archdeaconry in the diocese of Lichfield comprising the six deaneries of Derby, Ashbourne, High Peak, Castellar, Chesterfield and Repton. In 1884 it was transferred to the newly formed diocese of Southwell, but in 1927 was created a separate diocese of Derby, which includes the whole county except three parishes in the diocese of Peterborough. The assizes for Nottinghamshire and Derbyshire were held at Nottingham until the reign of Henry III, when they were held alternately at Nottingham and Derby until 1566, after which the Derbyshire assizes were held at Derby. The miners of Derbyshire formed an independent community under the jurisdiction of a steward and barmasters, who held two Barmote courts (*q v*) every year. The forests of Peak and Duffield had their separate courts and officers.

At the time of Domesday Henry de Ferrers owned almost the whole of the modern hundred of Appleton. The Ferrers estates were forfeited by Robert earl of Derby, in the reign of Henry III. Another Domesday landholder was William Peverel, the founder of Peak castle, whose possessions were known as the honour of Peverel. In 1155 the estates were forfeited to the crown. During the reigns of John and Henry III discontent was rife in Derbyshire and attacks were made on the central power. Riots occurred in 1443. In the 17th century the county first supported the king, but by 1643 Sir John Gell of Hopton had secured almost the whole county for the parliament. Derby, however, was always royalist and Romanist in sympathy, and in 1745 entertained the young pretender.

Agriculture and Industries.—Slightly over 67% of the total area of 639,120 ac was devoted to agriculture in 1939, but of this only 16% was arable land. Among the higher altitudes of north Derbyshire where the soil is poor and the climate harsh, grain is unable to flourish, while even in the more sheltered parts of this region the harvest is usually late. Such districts have heath pasture with sheep farming. Farther south are heavy crops of wheat and oats, while turnips and swedes and green crops are not uncommon. Some barley is cultivated about Repton and Gresley. Wheat (19,321 ac in 1939) is the most important crop in the county. A large part of the Trent valley is under permanent pasture, being devoted to cattle feeding and dairy farming. The National Trust owned 2,565 ac in the county in 1942.

Derbyshire has always been mainly a mining and manufacturing county, though the rich land in the south formerly produced large quantities of corn. The lead mines were worked by the Romans, and Domesday mentions lead mines at Wirksworth, Matlock, Bakewell, Ashford and Crich. Iron has also been produced in Derbyshire from an early date, and coal mines were worked at Norton and Alfreton in the beginning of the 14th century. The woollen industry flourished in the county before the reign of John, when an exclusive privilege of dyeing cloth was conceded to the burgesses of Derby. Thomas Fuller in 1663 mentions lead, malt and ale as the chief products of the county, and the Buxton waters were already famous in his day. The 18th century saw the rise of numerous manufactures. In 1718 Sir Thomas and John Lombe set up an improved silk-throwing machine at Derby, and in 1758 Jedediah Strutt introduced a machine for making stockings. In 1771 Sir Richard Arkwright set up one of his first cotton mills in Cromford, and in 1787 there were 22 cotton mills in the county. The Derby porcelain or china manufactory was started about 1750. The industrial districts, based on the coalfield, are in the east and extreme southwest. Silk, cotton, iron, papermaking, woollens, lace, malting and brewing are important. Derby, Belper and Duffield are the silk centres, while Derby has also its china, lace, braids, cords, chemical and motor (Rolls Royce) manufactures. Belper, Glossop, Ilkeston and Cromford specialize in cotton-spinning and hosiery. The iron smelting focuses on Alfreton, Chesterfield, Derby, Dronfield and Eckington. Lead, gypsum,

zinc, iron ore, manganese and barytes are raised to some extent. The county is famous for its limestone and marble quarries, while the fluorspar of the limestone caverns is made into ornaments. The warm mineral springs at Buxton, Matlock and Bakewell are well known.

The chief railway serving the county is the LMS, which has one of its chief works at Derby, while a branch of the LNE serves Derby and other places in the south. The Trent and Mersey canal crosses the southern part of the county, and there is a branch canal (the Derby) connecting Derby with this and with the Erewash canal, which runs north from the Trent up the Erewash valley. From it there is a little used branch (the Cromford canal) to Matlock. There were 2,395 mi. of roads in the county in 1942.

Population and Administration.—The area of the administrative county, which contains six hundreds, is 992.9 sq mi., pop (1938) 627,800. Wartime movements had little effect in Derby, the population rising only 1% between Sept. 1939 and Feb. 1941. Derby is a county borough, the municipal boroughs are Buxton, Chesterfield, Glossop and Ilkeston. The urban districts are Alfreton, Ashbourne, Bakewell, Belper, Bolsover, Chry Cross, Dronfield, Heanor, Long Eaton, Matlock, New Mills, Ripley, Staveley, Swadlincote District, Whaley Bridge and Wirksworth. The county is in the Midland circuit, and assizes are held at Derby. It has one court of quarter sessions and is divided into 15 petty sessional divisions. The boroughs of Derby, Chesterfield and Glossop have separate commissions of the peace, and that of Derby has also a separate court of quarter sessions. The total number of civil parishes is 310. The county returned two members to parliament from 1295 until 1832, after which it returned four members in two divisions until 1868 when six members were returned for three divisions. After 1918 the county returned eight members, one each for the following divisions: Belper, Chesterfield, Clay Cross, High Peak, Ilkeston, Northeastern, Southern and Western, while the county borough of Derby returned two members after 1275.

DERBYSHIRE NECK. see GOITRE

DEREHAM, (properly East Dereham), market town and urban district in Norfolk, England, 122 mi. NNE from London. Pop (est. 1938) 5,730. Area, 8.9 sq mi. The church of St Nicholas is a cruciform Perpendicular structure with a beautiful central tower and some portions of earlier date. It contains a monument to William Cowper, who came to live here in 1796, and the Congregational chapel stands on the site of the house where the poet spent his last days. Dereham is an important agricultural centre, and has a large Friday market. There is an annual harvest fair in September. The manufactures are agricultural steam engines and threshing machines, there is also a coach works.

DERELICT, in law, property thrown away or abandoned by the owner in such a manner as to indicate that he intends to make no further claim to it. The word is used more particularly with respect to property abandoned at sea (see **WRECK**). Land gained gradually and slowly from the sea belongs to the owner of the adjoining land by *dereliction*, but in England in the case of sudden or considerable recession, the land belongs to the crown.

DERENBOURG, HARTWIG (1844–1908), French orientalist, son of the following, was born in Paris on June 17, 1844. He studied at Göttingen, Leipzig and at the École des Langues Orientales, Paris. In 1879 he was appointed professor of Arabic

at the École des Hautes Études in Paris. He collaborated with his father in the great edition of Seadiab (1893 etc.) and the edition of Abu-l-Wahid, and also prepared a number of important editions of other Arabic writers and a catalogue of the Arabic mss in the Escorial (2 vols 1884-93).

DERENBOURG, JOSEPH (1811-1895), Franco-German orientalist, was born at Mainz on Aug. 21, 1811, and settled in Paris in 1839. He was a considerable force in the revival of Jewish education in France. He made great contributions to the knowledge of Seadiab (*q.v.*), and planned a complete edition of Seadiab's works in Arabic and French. Among his numerous works is an *Essai sur l'histoire et la géographie de la Palestine* (Paris, 1867). This was an original contribution to the history of the Jews and Judaism in the time of Christ, and has been much used by later writers on the subject (*e.g.*, Schurer). He became professor of Hebrew and rabbinical theology at the École des Hautes Études, Paris, in 1877. Derenbourg died on July 29, 1895, at Embs.

DERG, LOUGH, a lake of Ireland, on the boundary of the counties Galway, Clare and Tipperary. It is an expansion of the Shannon channel, 23 m long and from 1 to 3 m broad. The water appears to be dammed, as the Shannon flowing over the low lying central plain breaks through the narrow gorge between Sheve Bernagh and the Arra mountains. Ruined churches and fortresses are numerous on the eastern shore, and on Inisicaltra island are a round tower and the remains of five churches.

Another LOUGH DERG, near Pettigo in Donegal, is famous as the traditional scene of St Patrick's purgatory. In the middle ages its pilgrimages had a European reputation, and they are still observed. The hospice, chapels, etc., are on Station island, and there is a ruined monastery on Saints' island.

DE RIDDER, a city of south-western Louisiana, U.S.A., on the watershed between the Sabine and the Calcasieu rivers, the capital of Beauregard parish. It is on Federal highway 171, and is served by the Santa Fe, the Kansas City Southern and the Southern Pacific railways. The population was 5,776 in 1950 and 3,750 in 1940 by the federal census. It was founded in 1900 as a pine milling centre, and with the decline of that industry (about 1920) a study of the agricultural possibilities of the region was made, and the cultivation of satsuma oranges, grapefruit and lemons was introduced. By 1927 there were 400,000 citrus trees growing in the vicinity, of which 25,000 were already bearing full crops. De Ridder was organized as a city in 1912. It has a commission form of government.

D'ERLON, JEAN BAPTISTE DROUET, COUNT (1765-1844), marshal of France, was born at Reims on July 29, 1765. He entered the army as a private soldier in 1782, did good service in the campaigns of the revolutionary wars, and in 1799 attained the rank of general of brigade. He served in Switzerland under Masséna (1799), at Hohenlinden under Moreau (1800), at Jena (1806), and at Friedland (1807). After this last battle he was created count d'Erlon and received a pension. For the next six years d'Erlon was almost continuously engaged as commander of an army corps in the Peninsular War. At the pass of Maya in the Pyrenees he defeated (1814) Lord Hill's troops. After the first Restoration he was named commander of the 16th military division, but was arrested for conspiring with the Orleans party. He escaped, and joined Napoleon on his return from Elba. The emperor made him peer of France, and gave him command of the 1st army corps. In the Waterloo campaign d'Erlon's corps formed part of Ney's command on June 16 but, in consequence of an extraordinary series of misunderstandings took part neither at Ligny nor at Quatre Bras (*see* WATERLOO CAMPAIGN, 1815).

He was in command of the right wing of the French army throughout the great battle of June 18 and fought in the closing operations around Paris. At the second Restoration d'Erlon fled into Germany, only returning to France after the amnesty of 1825. He was reinstated on the accession of Louis Philippe. As commander of the 12th military division (Nantes) he suppressed the legitimist agitation in his district and caused the arrest of the duc de Berry (1832). He was governor of Algeria from 1834 to 1836. D'Erlon was made marshal of France shortly before his

death in Paris on Jan. 25, 1844.

DERMAPTERA, an order of insects (*q.v.*), which includes the earwigs (*q.v.*).

DERMATOLOGY *see* SKIN DISEASES

DERMOT MAC MURROUGH (d. 1171), Irish king of Leinster, succeeded his father in the principality of the Hu Cn sellagh (1115) and eventually in the kingship of Leinster. About 1152 we find him engaged in a feud with O Ruairc, the lord of Breifne (Leitrim and Cavan). Dermot abducted the wife of O Ruairc more with the object of injuring his rival than from any love of the lady. The injured husband called to his aid Roderic, the high king (airdrigh) of Connaught, and in 1166 Dermot fled before this powerful coalition to invoke the aid of England. Obtaining from Henry II a license to enlist allies among the Welsh marchers, Dermot secured the aid of the Clares and Geraldines. To Richard Strongbow, earl of Pembroke and head of the house of Clare, Dermot gave his daughter Eva in marriage, and on his death was succeeded by the earl in Leinster. The historical importance of Dermot lies in the fact that he was the means of introducing the English into Ireland. Through his aid the towns of Waterford, Wexford and Dublin had already become English colonies before the arrival of Henry II in the island. To the credit of Dermot Mac Murrough must be put the compilation of the *Book of Leinster*, a valuable collection of early Gaelic tradition.

See The Song of Dermot and the Earl, an old French Poem (by M. Regan?), edit. with trans. by G. H. Orpen (1892), Kate Norgate, England under the Angevin Kings, vol. II.

DERNA, a town on the north coast of Cyrenaica, Africa (anc. *Darnus-Zarne*), 224 m E of Bengasi by road (railway as far as El Merg). Population (1938) 21,547. Situated below the eastern butt of Jebel Akhdar on a small but rich deltaic plain, watered by fine perennial springs, it has a growing population and trades in fruits grown in its extensive palm gardens, and in hides and wool brought down by the nomads from the interior. The bay is open from north-west round to south-east and often inaccessible in winter and spring. A portion of the people is of Moorish stock, of Andalusian origin, which emigrated in 1493, the descendants preserve a fine racial type. It was the easternmost city of the Pentapolis of Cyrenaica. There is a highhouse west of the bay. The names Darnus and Zarne are philologically identical and probably refer to the same place. No traces are left of the ancient town except some rock tombs. Darnus continued to be of some importance in early Muslim times as a station on the Alexandria-Kairouan road, and has served on more than one occasion as a base for Egyptian attacks on Cyrenaica and Tripolitania. In 1805 the government of the United States, in dispute with the dey of Tripoli on account of piracies on American shipping, landed a force under William Eaton (*q.v.*) to co-operate in the attack on Derna then being made by Sidi Ahmet, an elder brother of the dey. After 1835 Derna passed under direct Ottoman control, and subsequently served as the point whence the sultan exerted a precarious but increasing control over eastern Cyrenaica and Marmarica. It passed to Italy in 1912. There is a caravan route to Tobruk (115 mi).

DERNBURG, HEINRICH (1829-1907), German legal scholar, was born on March 3, 1829, at Mainz, and died at Berlin on Nov. 23, 1907. He was made professor at Zurich (1854), at Halle (1862), at Berlin (1873) and from 1866 was in the Prussian Upper House. His chief publications are *Die Kompensation* (1854), *Das Pfandrecht* (2 vols, 1860), *Die Institutionen des Caus* (1860), *Lehrbuch des preuss. Privatrechts* (3 vols, 1871-96), *Pandekten* (3 vols, 1884), and *Das bürgerliche Recht des Deutschen Reichs u. Preussens* (5 vols, 1898).

DÉROULEDE, PAUL (1846-1914), French author and politician, was born in Paris. His first published works appeared in the *Revue nationale*, under the pseudonym of Jean Rebel, and in 1869 he produced at the Théâtre Français a one-act drama in verse entitled *Juan Sirener*. On the outbreak of the Franco-Prussian War he enlisted as a private, was wounded and taken prisoner at Sedan, and sent to Breslau, but effected his escape. He then served under Chanzy and Bourbaki, took part in the latter's disastrous retreat to Switzerland and fought against the Commune in Paris. After attaining the rank of lieutenant, he

was forced by an accident to retire from the army. He published in 1872 a number of patriotic poems (*Chants du soldat*), which enjoyed unbounded popularity. This was followed in 1875 by another collection, *Nouveaux Chants du soldat*. In 1877 he produced a drama in verse called *L'Esleman*, which derived a passing success from the patriotic fervour of its sentiments. For the exhibition of 1878 he wrote a hymn, *Vive la France*, which was set to music by Gounod. In 1880 his drama in verse, *La Moabite*, which had been accepted by the Theatre Français, was forbidden by the censor on religious grounds.

In 1882 M. Deroulde founded the *Ligue des patriotes*, with the object of furthering France's "revanche" against Germany. He was one of the first advocates of a Franco-Russian alliance, and as early as 1883 undertook a journey to Russia for the furtherance of that object. On the rise of General Boulanger M. Deroulde attempted to use the *Ligue des patriotes*, hitherto a non political organization, to assist his cause, but was deserted by a great part of the league and forced to resign his presidency. Nevertheless he used the section that remained faithful to him with such effect that the Government found it necessary in 1889 to decree its suppression. In the same year he was elected to the chamber as member for Angoulême. He was expelled from the chamber in 1890 for his disorderly interruptions during debate. He did not stand at the elections of 1893, but was re-elected in 1898. After the funeral of President Faure, on Feb. 23, 1899, he endeavoured to persuade Gen. Roget to lead his troops upon the Elysée. For this he was arrested, but on being tried for treason was acquitted (May 31). On Aug. 12 he was again arrested and accused, together with André Buffet, Jules Guerin and others, of conspiracy against the republic. After a long trial before the high court, he was sentenced, on Jan. 4, 1900, to ten years' banishment from France, and retired to San Sebastian. In Nov. 1905, however, the law of amnesty enabled him to return to France. He died near Nice on Jan. 30, 1914.

Besides the works already mentioned, he published *Le Sergent*, in the *Théâtre de campagne* (1880), *De l'éducation militaire* (1882), *Monsieur le Hulan et les trois couleurs* (1884), *Le Premier grenadier de France*, *La Tour d'Auvergne* (1886), *Le Livre de la ligue des patriotes* (1887), *Refrains militaires* (1888), *His toire d'amour* (1890), a pamphlet entitled *Désarmement?* (1891), *Chants du paysan* (1894), *Poèmes militaires* (1895) and *Messure du Gueschn, drame en vers* (1895), *La mort de Hoche* (1897), *La Plus belle fille du monde, conte dialogué en vers libres* (1898), 1870, *Feuilles de route* (1907), a volume of reminiscences.

DERRICK, a type of crane, the name is derived from that of a famous early 17th-century Tyburn hangman, and was originally applied as a synonym (*see* CRANES). The derrick of the petroleum industry is a skeleton framework or tower of wood or steel for hoisting or lowering from a fixed point. It is used to raise and drop the drilling tools and also to insert and remove the well casing or pipe.

DERRING-DO, valour, chivalrous conduct or "desperate courage." The word is a misconstruction of the verbal substantive *dorryng* or *durring*, "daring," and the present infinitive of "do." Edmund Spenser first adapted *derring-do* as a substantive meaning "manhood and chivalry," and this use was revived by Sir Walter Scott.

DERRY, a town of Rockingham county, N.H., on Beaver brook, 10 mi. S.E. of Manchester, served by the Boston and Maine railroad. The population was 5,798 in 1950. It is a summer resort, and manufactures shoes.

DE RUYTER, MICHAEL ADRIANZON (1607-1676), Dutch naval officer, was born at Flushing on March 24, 1607. In 1636 he was entrusted by the merchants of Flushing with the command of a cruiser against the French pirates. In 1640 he entered the service of the United Provinces, and, being appointed rear admiral of a fleet fitted out to assist Portugal against Spain, specially distinguished himself at Cape St. Vincent, Nov. 3, 1641. In the following year he left the service of the United Provinces to command a merchant vessel. In 1652 a squadron of five vessels was despatched against the English, under the command of Admiral Tromp. De Ruyter, who accompanied the admiral in this

expedition, seconded him with great skill and bravery in the three battles which were fought with the English off Plymouth, the Kentish Knock, and Dungeness. He was afterwards stationed in the Mediterranean, where he captured several Turkish vessels. In 1659 he received a commission to join the king of Denmark in his war with the Swedes. As a reward for his services, the king of Denmark ennobled him and gave him a pension. In 1661 he grounded a vessel belonging to Tunis, released forty Christian slaves, made a treaty with the Tunisians, and reduced the Algerine corsairs to submission. He recaptured English settlements on the west coast of Africa but was repulsed at Barkad and failed to recover New Amsterdam. He returned to take command of a large fleet which had been organized against England, and in May of the following year, after a long contest off the North Foreland, he compelled the English to take refuge in the Thames and burnt the "King Charles" and other warships in the Medway. On June 7, 1672, he fought a drawn battle with the combined fleets of England and France, in Southwold bay, and conveyed safely a fleet of merchantmen. In 1676 he assisted Spain against France in the Mediterranean, and receiving a mortal wound in the battle on April 22, off Messina, died on the 29th at Syracuse. His body was carried to Amsterdam where a magnificent monument to his memory was erected by command of the States General (*See* also DUTCH WARS).

See *Life of De Ruyter* by Brandt (Amsterdam, 1687), and by Kloppe (2nd ed., Hünover, 1858).

DERVISH, a Persian word, meaning "beggar," generally in Islam a member of a religious fraternity, whether mendicant or not, but in Turkey and Persia more exactly a wandering begging religious, called, in Arabic speaking countries, a *faqir*. With its important differences, the dervish fraternities may be compared to the regular religious orders of Roman Christendom, while the *Ulema* (*q v*) are, also with important differences, like the secular clergy. For the origin and history of the mystical life in Islam, which led to the growth of the order of dervishes *see* SÖFISM, here an account is given of (1) the dervish fraternities, and (2) the Sūfi hierarchy.

1 **The Dervish Fraternities**—In the earlier times, the relation between devotees was that of master and pupil. Those in-

clined to the spiritual life gathered round the revealed shaykh (*murshid*, "guide," *ustādih*, *pīr*, "teacher"), lived with him, shared his religious practices and were instructed by him. In time of war against the unbelievers, they might accompany him to the threatened frontier, and fight under his eye. Thus *murābbit*, "one who pickets his horse on a hostile frontier," has become the *marabout* (*q v*) or dervish of Algeria, and *ribāt*, "a frontier fort," has come to mean a monastery. The relation, also, might be for a time only. The pupil might at any time return to the world, when his reli-

gious education and training were complete. Continuous corporations began to be formed in the 12th century. Many existing orders trace their origin to saints of the 3rd, 2nd and even 1st Muslim centuries, e.g., to either Ali or Abū Bakr, and in Egypt all are under the rule of a direct descendant of the latter, but such ascription is purely legendary.

Of these orders, 32 are commonly reckoned, but many have vanished or have been suppressed, and there are sub orders innumerable. Each has a "rule" dating back to its founder and a ritual which the members perform when they meet together in their convent (*khanqāh*, *ṣāḥibya*, *takrya*). This may consist simply in the repetition of sacred phrases, or it may be an elaborate performance, such as the whirling of the dancing dervishes, the Mawlawis, an order founded by Jalāl ud-Dīn ar Rūmī, the most broad-minded and tolerant of all. There are also the performances of the Rifāʾi or "howling dervishes". In ecstasy they cut themselves with knives, eat live coals and glass, handle red hot iron and devour serpents. They profess miraculous healing powers, and the head of the Saḍīs, a sub order, used, in Cairo, to ride over the bodies of his dervishes without hurting them, the so called *Dösch* (*dausa*). Another division is made by their attitude to the law of Islam. Some neglect in general the ceremonial and ritual law, to such an extent that in Persia, India and Turkey dervish orders are classified as *bā shā*, "with law," and *bi-shā*, "without law." The latter are really antinomians, and the best example of them is the Baktāshī order, widely spread and influential in Turkey and Albania and connected by legend with the origin of the Janissaries. The Santūs was the last order to appear, and is distinguished from the others by a severely puritanic and reforming attitude and strict orthodoxy, without any admixture of mystical slackness in faith or conduct. Each order is distinguished by a peculiar garb. Candidates for admission have to pass through a novitiate, more or less lengthy. First comes the *ahd*, or initial covenant, in which the neophyte or *murīd*, "seeker," repents of his past sins and takes the shaykh of the order he enters as his guide (*murshīd*) for the future. He then enters upon a course of instruction and discipline, called a "path" (*ṭarīqa*), on which he advances through diverse "stations" (*maqāmāt*) or "passes" (*aqabat*) of the spiritual life. The Mawlawis have the most severe novitiate. Their aspirant has to labour as a lay servant of the lowest rank for 1,000 days before he can be received. For one day's failure he must begin again from the beginning.

But besides these full members there is an enormous number of lay adherents, like the tertiaries of the Franciscans. Thus, nearly every religious man of the Turkish Muslim world is a lay member of one order or another, under the duty of saying certain prayers daily. Certain trades, too, affect certain orders. Most of the Egyptian Qāḍīs, for example, are fishermen and, on festival days, carry as banners nets of various colours. On this side, the orders bear a striking resemblance to lodges of Freemasons and other friendly societies, and points of direct contact have even been alleged between the more pytheistic and antinomian orders, such as the Baktāshī, and European Freemasonry. They are the only ecclesiastical organization that Islam has ever known, but it is a multifarious organization, unclassified internally or externally. They differ thus from the Roman monastic orders, in that they are independent and self developing, each going its own way in faith and practice, limited only by the universal conscience (*ʿimā*, "agreement," see ISLAMIC LAW) of Islam.

2 Saints and the Sūfī Hierarchy.—That an elaborate doctrine of wonder-working saints should have grown up in Islam may, at first sight, appear an extreme paradox. It can, however, be conditioned and explained. First, Muhammad left undoubted loop-holes for a minor inspiration, legitimate and illegitimate. Secondly, the Sūfīs, under various foreign influences, developed these to the fullest. Thirdly, just as the Christian church has absorbed much of the mythology of the supposed exterminated heathen religions into its cult of local saints, so Islam, to an even higher degree, has been overlaid and almost buried by the superstitions of the peoples to which it has gone. Their religious and legal customs have completely overcome the direct commands of

the Qurʾān, the traditions from Muhammad and even the "Agreement" of the rest of the Muslim world (see ISLAMIC LAW). The worship of saints, therefore, has appeared everywhere in Islam with an absolute belief in their miracles and in the value of their intercession, living or dead.

Further, there appeared very early in Islam a belief that there was always in existence some individual in direct intercourse with God and having the right and duty of teaching and ruling all mankind. This individual might be visible or invisible, his right to rule continued. This is the basis of the Ismāʾīlī and Shīʾī position (see the article ISLAMIC INSTITUTIONS). The Sūfīs applied this idea of divine right to the doctrine of saints, and developed it into the Sūfī hierarchy. This is a single, great, invisible organization forming a sanely board of administration, by which the invisible government of the world is supposed to be carried on. Its head is called the *Qutb* (Axis), he is presumably the greatest saint of the time, is chosen by God for the office and given greater miraculous powers and rights of intercession than any other saint enjoys. He wanders through the world, often invisible and always unknown, performing the duties of his office. Under him there is an elaborate organization of *walīs*, of different ranks and powers, according to their sanctity and faith. The term *walī* is applied to a saint because of Kor x 63, "Ho! the *walīs* of God, there is no fear upon them, nor do they grieve," where *walīs* means "one who is near," friend or favourite.

In the fraternities, then, all are dervishes, clustered or lay, whose whose faith is so great that God has given them miraculous powers—and there are many—are *walīs*, begging *ḥuqūq* are *Jaḥirs*. All forms of life—solitary, monastic, secular, celibate, married, wandering, stationary, ascetic, free—are open. Their theology is some form of Sūfism.

DERWENT, the name of several English rivers (Celtic *Dwr* gent, clear water). (1) The Yorkshire Derwent drains North Yorkshire moors, rising in their eastern part. A southern head-stream, however, rises in the Yorkshire wolds near Filey, about a mile from the North Sea, but it flows inland owing to a coast moraine deposit. The early course of the Derwent lies through the flat open vale of Pickering between the Yorkshire moors and the Yorkshire wolds, the upper part of which is known as the Carrs, when the river follows an artificial drainage cut. It receives many tributaries from the moors, then breaches the low hills below Malton, and reaches the central plain of Yorkshire. Its direction hitherto westerly, now becomes southerly, roughly parallel to the Ouse, which it joins near Barmby on the Marsh, after a course, of about 70 m. As a tributary of the Ouse it is included in the Humber basin. It is tidal up to Sutton-upon Derwent, 15 m from the junction with the Ouse, and is locked up to Malton, but the navigation is little used. A canal leads east from the tidal water to the market town of Pocklington.

(2) The Derbyshire Derwent rises in Bleaklow hill north of the Peak and traverses a narrow dale, which, with the tributaries, the Noe, watering Hope valley, and the Wye, is famous for its beauty (see DERBYSHIRE). The Derwent flows south past Chatsworth, Matlock and Belper and then, passing Derby, debouches upon a low plain, and turns south eastward, to join the Trent, after flowing 60 m., near Sawley. It falls in all some 1,700 ft. (from Matlock 200 ft.), and no part is navigable, save certain reaches at Matlock and elsewhere for pleasure boats.

(3) The Cumberland Derwent rises below Great End in the Lake District, draining Spinkling and Sty Head tarns, and flows through Borrowdale, receiving a tributary from Lang Strath. It then drains the lakes of Derwentwater and Bassenthwaite, after

which its course, hitherto northerly becomes westerly past Cockermouth to the Irish Sea at Workington. The length is about 34 m, and the fall about 2,000 ft. (from Derwentwater 244 ft.), the waters are beautifully clear, and the river is not navigable. At a former period Derwentwater and Bassenthwaite formed one lake, but they have been separated by lacustrine deltas at the mouths of the river Greta, which now joins the Derwent immediately below Derwentwater, and the Newlands Beck, which enters Bassenthwaite.

(4) A river Derwent rises in the Pennines near the borders of Northumberland and Durham, and forming a large part of the boundary between these counties, takes a north easterly course of 30 m to the Tyne, which it joins 3 m above Newcastle.

DERWENT, the principal river of Tasmania, with a length of 130 miles. It rises in Lake St. Clair and flows south west, entering Storm Bay at Hobart by an estuary four miles wide. See TASMANIA.

DERWENTWATER, EARL OF, an English title borne by the family of Radclyffe or Radcliffe from 1688 to 1716, when the 3rd earl was attainted and beheaded, and claimed by his descendants, adherents of the exiled house of Stuart, from that date until the death of the last male heir in 1814. Sir Francis Radclyffe, 3rd baronet (1625-1697), was the lineal descendant of Sir Nicholas Radclyffe, who acquired the extensive Derwentwater estates in 1417 through his marriage with the heiress of John de Derwentwater, and of Sir Francis Radclyffe, who was made a baronet in 1619. In 1688 Sir Francis was created Viscount Radclyffe and earl of Derwentwater by James II, and dying in 1697 was succeeded as 2nd earl by his eldest son Edward (1655-1705), who had married Lady Mary Tudor (d. 1726), a natural daughter of Charles II. The 2nd earl died in 1705, and was succeeded by his eldest son James (1689-1716), who was born in London on June 28, 1689, and was brought up at the court of the Stuarts in France as companion to Prince James Edward, the old Pretender. In 1710 he came to reside on his English estates. Joining the Stuart rising of 1715, Derwentwater escaped arrest owing to the devotion of his tenantry, and in October, with about 70 followers, he joined Thomas Forster at Greenrig. When the rebels capitulated at Preston he was conveyed to London and impeached. Pleading guilty at his trial he was attainted, and was beheaded on Tower Hill on Feb. 24, 1716, declaring on the scaffold his devotion to the Roman Catholic religion and to King James III.

On the death of the 3rd earl's son, John Radclyffe, in 1731 his uncle Charles (1693-1746), son of the 2nd earl, took the title of earl of Derwentwater. Charles Radclyffe had fought at Preston and was condemned to death for high treason, but, more fortunate than James, he escaped from prison and went to live in Rome. He was captured by an English ship in Nov. 1745 whilst proceeding to join Charles Edward, the young Pretender, in Scotland. He was beheaded on Dec. 8, 1746. His eldest son, James Bartholomew (1725-1786), who had shared his father's imprisonment, then claimed the title of earl of Derwentwater, and on his mother's death in 1755 became 3rd earl of Newburgh. His only son and successor, Anthony James (1757-1814), died without issue in 1814, when the title became extinct *de facto* as well as *de jure*. The present representative of the Radclyffe family is Lord Petre, and in 1874 the bodies of the first three earls of Derwentwater were reburied in the family vault of the Petres at Thorndon, Essex.

See R. Patten, *History of the Late Rebellion* (London, 1717); W. S. Gibson, *Diston Hall, or Memoirs of James Radclyffe, earl of Derwentwater* (London, 1848-1850); G. E. C. (okayne), *Complete Peerage* (Exeter, 1887-1898), and *Dictionary of National Biography*, vol. xlvii (London, 1896).

DERWENTWATER, a lake of Cumberland, England, in the Lake District (qv). It is approximately oval in shape, about 3 m long and from $\frac{1}{2}$ m to $\frac{1}{4}$ m wide. The greatest depth is 70 feet. The lake is seen at one view, within an amphitheatre of mountains of varied outline, overlooked by others of greater height. Several elevations near the lake are famous view-points, e.g., Castle Head, Walls Crag, Ladder Brow and Cat Bells. The shores are well wooded, and the lake is studded with several islands, of which Lord's Island, Derwent Isle and St. Herbert's

are the principal. Lord's Island was the residence of the earls of Derwentwater. St. Herbert's Isle is so called because here lived St. Herbert, mentioned by Bede, in the 7th century. Derwent Isle (6 acres) contains a handsome residence surrounded by lawns, gardens and timber of large growth. The Falls of Lodore, at the upper end of the lake, consist of a series of cascades in the small Watendlath beck, which falls over crags from a height of nearly 200 feet. The "Floating Island" appears at intervals on the upper portion of the lake near the mouth of the beck, and is formed by the accumulation of decayed vegetable matter floating on the water. The river Derwent (qv) enters the lake from the south and leaves it on the north, draining it through Bassenthwaite lake, which is separated from Derwentwater by a lacustrine delta, to the Irish Sea. To the north east of the lake lies the town of Keswick.

DERZHAVIN, GAVRILA ROMANOVICH (1743-1816), Russian poet, was born at Kazan on July 14, 1743. He entered the army in 1762, was governor of Olonets (1784), Tambov (1785), and then secretary for petitions under Catherine II, to whom many of his odes are addressed. Under Alexander I he was for a short time minister of justice, but in 1803 he retired to his estate at Zvanka, in the Novgorod Government, where he spent a serene and gay old age in the pursuit of letters. He died at Zvanka on July 21, 1816. Derzhavin, says Prince Minsky "for sheer imaginative power is one of the small number of Russia's greatest poets." His *Ode to God* (Eng. trans. Sir John Bowring, 1861), was one of his most famous poems and was translated into many European languages.

His works were edited by Grot (7 vols., 1864-73), who also wrote his biography (2 vols., 1886-87). His poems were translated into German by Kotzebue (1793). For translations of several of Derzhavin's poems into English see L. Wiener, *Anthology of Russian Literature* (1902) and Sir John Bowring, *Specimens of the Russian Poets* (1821).

DES ADRETS, FRANÇOIS DE BEAUMONT, BARON (c. 1512-1587), French Protestant leader, was born in 1512 or 1513 at the château de La Frette (Isère). In 1562, he joined the Huguenots, probably from motives of ambition and personal dislike of the house of Guise, and waged a successful campaign against the Catholics. In June of that year Des Adrets was master of the greater part of Dauphiné. The reprisals he exacted from the Catholics after their massacres of the Huguenots at Orange have left a dark stain upon his name. The garrisons that resisted him were brutally butchered, and at Montbrison, in Forez, he forced 18 prisoners to precipitate themselves from the top of the keep. Having alienated the Huguenots by his pride and violence, he entered into communication with the Catholics and declared himself openly in favour of conciliation. On Jan. 10, 1563, he was arrested on suspicion by some Huguenot officers and confined for a time in the citadel of Nîmes. He died, a Catholic, on Feb. 2, 1587.

See J. Roman, *Document inédit sur le baron des Adrets* (1878), and memoirs and histories of the time. See also Guy Allard, *Vie de François de Beaumont* (1675), l'abbé J. C. Martin, *Histoire politique et militaire de François de Beaumont* (1803), Eugène and Émile Haag, *La France protestante* (2nd ed., 1877).

DESAIX DE VEYGOUX, LOUIS CHARLES ANTOINE (1768-1800), French general, was born at Saint-Hilaire d'Ayat of noble parentage on Aug. 17, 1768, and was educated for the army. In 1789 he declared for the Revolution, and rose rapidly in the revolutionary army. By 1794 he had attained the rank of general of division. In the campaign of 1795 he commanded Jourdan's right wing, and in Moreau's invasion of Bavaria in 1796 he held an equally important command. In the retreat after the battles of Amberg and Würzburg (see FRENCH REVOLUTIONARY WARS) Desaix commanded Moreau's rearguard, and later the fortress of Kehl. He then obtained a mission to Italy, and met Bonaparte. Provisionally appointed commander of the "Army of England," Desaix was soon transferred by Bonaparte to the expeditionary force intended for Egypt. His division bore the brunt of the Mameluke attack at the battle of the Pyramids, and he defeated Murad Bey's army in Upper Egypt. Amongst the fellahs he acquired the significant appellation of the "Just Sultan." Desaix was one of the small party selected to accompany Bonaparte on his return to France, but the campaign of 1800 was well on its

way to the climax when Desaix was able to report himself for duty in Italy. He was in command of a corps of two infantry divisions when (June 14) he heard the cannon of Marengo on his right. He marched at once towards the sound, meeting Bonaparte's staff officer, who had come to recall him, half way on the route. He arrived with Boudet's division at the moment when the Austrians were victorious all along the line. Exclaiming, "There is yet time to win another battle!" he led his three regiments straight against the enemy's centre. At the moment of victory Desaix was killed by a musket ball. Napoleon erected the monuments to his memory on the Place Dauphine and the Place des Victoires in Paris.

See F. Marthas Beker, Comte de Mons, *Le Général L. C. A. Desaix* (1852).

DESARGUES, GERARD (1593-1662), French mathematician, was born at Lyons. By profession he was an engineer and architect, and was an army officer in the engineering section at the siege of La Rochelle. Between 1626 and 1630 he gave a series of lectures on mathematics at Paris, and influenced Descartes and Pascal. He died at Lyons in 1662. Most of his mathematical work is on geometry, and the theory of involution and transversals is due to him. Desargues' most important writings are *Traité de la section Perspective* (1636) and *Brouillon Project* (1639). The latter book deals with conics and embodies most of his researches.

DESÀUGIERS, MARC ANTOINE MADELEINE (1772-1827), French dramatist and song writer, son of Marc Antoine Désaugiers, musical composer, was born at Fréjus (Var). At the Revolution he emigrated to St. Domingo, and during the negro revolt he was made prisoner, barely escaping with his life. He took refuge in the United States, where he supported himself by teaching the piano. In 1797 he returned to his native country, and rapidly won fame as a writer of comedies, operas and vaudevilles, produced at the Théâtre des Variétés and the Vaudeville. He also wrote convivial and satirical songs, which, though different in character, can only worthily be compared with those of Beranger. He was at one time president of the *Caveau*, to which he introduced Béranger. In 1815 Désaugiers succeeded Pierre Yves Barré as manager of the Vaudeville. He died in Paris on Aug. 9, 1827.

An edition of Désaugiers' *Chansons et Poésies diverses* appeared in 1827. A new selection with a notice by Alfred de Bougy appeared in 1858. See also Sainte-Beuve's *Portraits contemporains*, vol. v.

DESAULT, PIERRE JOSEPH (1744-1795), French anatomist and surgeon, was born at Magny-Vernois (Haute Saône) on Feb. 6, 1744. He served as an apprentice in the military hospital of Belfort, and in 1782 he was appointed surgeon-major to the hospital *De la Charité*, and in 1788 to the Hôtel Dieu. The clinical school of surgery which he instituted at the Hôtel Dieu attracted great numbers of students, not only from every part of France but also from other countries, and he frequently had an audience of about 600. He died in Paris on June 1, 1795. Together with François Chopard (1743-95) he published a *Traité des maladies chirurgicales* (1770), and Bichat published a digest of his surgical doctrines in *Oeuvres chirurgicales de Desault* (1798-99).

DESBOROUGH, JOHN (1608-1680), English soldier and politician, son of James Desborough of Eltisley, Cambs., married in 1636 Eltisley Jane, daughter of Robert Cromwell of Huntingdon, and sister of the future Protector. He fought on the parliamentary side in the Civil War, but avoided all participation in the trial of the king in Jan. 1649, being employed in the settlement of the west of England. He fought at Worcester as major-general and nearly captured Charles II. near Salisbury. During the Commonwealth he held many high offices and was a member of the parliaments of 1653, 1654 and 1656. In spite of his near relationship to the Protector's family, he violently opposed the assumption by Cromwell of the royal title, and after the Protector's death he was, with Fleetwood, the chief instigator and organizer of the hostility of the army towards Richard Cromwell's Administration, and forced him to dissolve his parliament in April 1659. He was chosen a member of the council of State by the restored Rump, but presenting with other officers a seditious

petition from the army council, on Oct. 5, was dismissed. On the return of the Rump, Desborough was ordered to quit London. The reign of the new military Government was brief and inglorious, and after the Restoration he escaped to Holland where he engaged in republican intrigues. He was ordered home, in April 1666, on pain of incurring the charge of treason, and was imprisoned in the Tower till Feb. 1667. Desborough's rough person and manners are the constant theme of ridicule in the royalist ballads, and he is caricatured in Butler's *Hudibras* and in the *Parable of the Lion and Fox*.

DESCANT or DISCANT, a musical term much employed in earlier centuries, when it had various meanings. Thus it was at one time a term for any kind of polyphony and even for musical composition in general. In a more special sense it signified the addition of one part to another and was thus the earliest term for counterpoint. In part music it meant the upper part or voice, especially the soprano or melody, while it also signified at a later period an instrumental piece consisting of what would be called nowadays a theme with variations. In modern usage, however, descant means primarily the early art of counterpoint, with its various rules and theories and successive forms, as practised from the 12th century onwards. What was known as the descant clef was the C, or treble, clef, with the sign placed on the lowest line of the staff. (See *CLEF*.)

DESCARTES, RENE (1596-1650), French philosopher and man of science. The name is sometimes given as Des Cartes, and sometimes in the Latinized form, Renatus Cartesius (whence the term *Cartesian*).

LIFE AND WRITINGS

Descartes was born at La Haye, in Touraine, on March 31, 1596. His grandfather, Pierre Descartes, was a doctor in Châtelleraut, in Poitou, who married the daughter of a medical colleague there, named Ferrand, who eventually became rector of the University of Poitiers. Pierre's son, Joachim, was councillor of the parliament of Rennes, and so a member of the lesser nobility. He married Jeanne Brochard, the daughter of a high law-officer of Poitiers. René was their third child. The house in which he was born at La Haye was his mother's property which she had inherited from her mother. She died in May 1597, when René was little more than a year old. About ten years later Joachim Descartes moved to Brittany, where he married a second time. Various members of the Descartes and Brochard families were men of learning, so that the scientific attainments of René Descartes were not really as exceptional as used to be supposed when it was thought that his ancestry was essentially military. The story of his military ancestry must be dismissed as a legend based on a confusion between his medical grandfather and an army officer of the same name.

Physically René Descartes was never robust. But already at an early age he displayed remarkable mental vigour, so that his father was wont to refer to him as his "little philosopher." In 1604, at the age of eight, he was sent to the Jesuit school at La Flèche, in Anjou. The school had only recently been founded and endowed by Henry IV. in the hope of ingratiating himself with the Jesuits, one of whom had tried to assassinate him in 1594. The rector of the school, during the latter part of Descartes' stay there, was Father Charlet, a kinsman of his, who naturally took a special interest in him. The teacher to whose special care he was entrusted was Father Dmet, who subsequently became confessor to Louis XIII. and Louis XIV. When Henry IV. was assassinated in 1610 Descartes was one of the pupils selected to receive the heart of the dead monarch for burial in the church of La Flèche.

The first five years of Descartes' school life were devoted to the then usual school subjects, especially to the classical languages. The last three years were devoted to the study of logic and ethics, mathematics and physics and metaphysics respectively. His health called for some special indulgence, and he was allowed to stay in bed as long as he liked. Then, as afterwards, a considerable part of his work appears to have been done in bed. But he had no difficulties with his studies. He mastered them with ease, distinguishing himself especially in mathematics. Many years afterwards he criticized rather severely the studies he had pursued at school.

But it is difficult to say to what extent, if any, those criticisms express his actual feelings while he was still at school. They were probably after-thoughts. In any case, they were not especially directed against his school, but rather (like Bacon's criticisms in the *Advancement of Learning*) against the general state of contemporary studies. Towards his school he always retained a feeling of warm attachment. Later, during his controversies with Bourdin and Voetius, he turned to his former school teacher, Father Dinet, for advice. And throughout his life Descartes showed a special regard for Jesuits. It seems to have been his greatest ambition in after years to get his own philosophy introduced at La Flèche and in other Jesuit colleges. But no details are available about his school life and friends. In later life he had among his intimate friends some former pupils of La Flèche, notably Marin Mersenne, who was about seven years his senior. But there is no evidence of their acquaintance prior to 1622.

Descartes left school in 1612, and appears to have studied from 1613-16 at the university of Poitiers, where he graduated in law in Nov. 1616. His older brother was already a lawyer, but he himself was not attracted by the legal profession, and seems to have been contemplating a military career. So he devoted himself to riding and fencing, and actually wrote an essay on the art of fencing. But next to nothing is known of his doings during 1613-17. In 1618 he left France apparently in search of military experience in Holland. He served as a gentleman volunteer in the army of the stadtholder, Prince Maurice of Nassau, at Breda. Of any real soldiering there is no evidence. His stay at Breda was only remarkable for his chance meeting with a brother mathematician, Isaac Beeckman, rector of the college at Dort. Mathematics was useful for military engineering, so there were a number of mathematicians in the stadtholder's entourage at Breda. In the absence of more urgent business some of them passed the time in propounding problems which they posted on the city walls with a challenge to others to solve them. One day Descartes was trying to get at the gist of such a challenge, which was written in Dutch. He turned to a bystander with the request to translate it for him into French or Latin. It happened to be Beeckman, who did as requested, and jestingly asked the French cadet to solve the problem. Descartes brought him the solution in a couple of days, and the chance acquaintances became friendly. Descartes gave Beeckman a manuscript *Essay on Algebra*, also a *Compendium of Music* (dated Breda, Dec. 31, 1618) which he dedicated to Beeckman. Some of the scant information about Descartes relating to this period consists of entries in the diary of Beeckman, which has fortunately been discovered in recent years.

In April 1619 Descartes left Holland. He had planned an extensive journey from Amsterdam to Copenhagen, and thence via Poland, Hungary and Bohemia to Bavaria. This very roundabout route to Bavaria seemed necessary because of the insecurity of the direct route from Holland to Bavaria owing to military conditions in the intervening area. But there is no evidence that Descartes carried out his plan. What is known is that he was in Frankfurt a M. that summer, and there witnessed the festivities in connection with the coronation of the emperor Ferdinand. The following autumn and winter he seems to have passed in a village near Ulm on the Danube. Ostensibly he was taking part in the military campaigns which marked the opening of the Thirty Years' War. In reality he seems to have been occupied with problems of mathematics. Ulm was noted for its mathematicians, including Faulhaber (a reputed Rosicrucian) whom Descartes most probably met there. His stay near Ulm was chiefly remarkable for a certain illumination and certain dreams which he experienced there. He appears to have spent much of his time in solitary brooding over the problem of human knowledge. Moods of doubt and darkness assailed him, and he prayed for light. Of all his studies up to that point only one had really satisfied him, namely, mathematics. And he attributed the certainty of mathematics to the character of its method. On Nov. 10, 1619, the thought appears to have flashed upon him suddenly that the mathematical method, or, more precisely, the method of analytical geometry, might be extended to other studies. The thought dominated his mind like a divine revelation. Three dreams followed. In the first he ap-

peared to be lame, and forced by a tempest to seek shelter in a church. In the second dream he heard the sound of thunder, and saw sparks of fire round about him. In the third he opened at random the poem of Ausonius, and his eyes fell on the words *Quid vias sectaberis?* (What way of life shall I follow?) The whole experience made such a deep impression on him that he vowed a pilgrimage to our Lady of Loretto. Whatever psycho-analytic interpretation one may put on the whole episode, there is no doubt of its profound effect on Descartes. He saw light, and it was probably at this period of his life that he arrived at his fundamental ideas relating to algebra, geometry and methodology. The years 1620-28 were no doubt devoted mainly to the elaboration and application of these ideas.

In 1620 Descartes visited Austria and Bohemia. He is reported to have served as a volunteer in the army of the duke of Bavaria against the protestant princes, and to have taken part in various battles, including that of the White Mountain, near Prague, which ended in the defeat of the Protestant princes and the downfall of Frederick V., father of the Princess Elizabeth of whom more will be said presently. But there is no reliable evidence for these dubious attempts to surround Descartes' head with a halo of military glory. Most probably he never smelled gunpowder. In April 1622 he was in France again, and stayed partly at Rennes and partly in Paris, until March 1623. He then went to Italy on certain family business. On May 16 (Ascension Day), 1624, he was in Venice and witnessed the symbolic ceremony of "the wedding of the sea" (the Adriatic). From Venice he went on his pilgrimage to our Lady of Loretto. Christmas 1624 saw him in Rome, where, in 1625, he witnessed the celebration of the Roman Catholic "Jubilee" (the Papal remission of the sins of the pilgrims). On his return he passed through Florence, but did not trouble to visit Galileo there. Indeed, in a subsequent letter, Descartes declared with emphasis that he had never learned anything from the writings of Galileo. The Loretto pilgrim could hardly have been expected to show sympathy for a semi heretic like Galileo.

It appears that about this time Descartes was seriously thinking of settling in Italy, but the heat was too much for him. So he returned to France, passing the next three years partly in the country and partly in Paris. His contact with learned men in Paris stimulated his philosophic and scientific ambitions. Cardinal Bérulle, Mersenne and Mydorge were particularly encouraging to him. For a time he carried on research in optics with the help of Fermier, a skilled maker of lenses. But the distractions of Paris were not conducive to fruitful work. Descartes consequently decided to move to some quiet place in Holland where he might devote his undivided attention to the problems of philosophy and science. He had seen enough of the bustle of the great world, and he longed for some quiet retreat where he might collect his

of a locality he always considered the opportunities they afforded of practising catholicism. His first home in Holland was at Franeker (near Groningen), where he stayed from 1628-30, and it was here that he wrote his *Rules for the Direction of the Mind*, in 1628 or 1629, though it was not published till 1701. It may be recalled that his earliest known compositions, namely, the *Essay on Algebra* and the *Compendium of Music*, were written in Breda in 1618. In fact nearly all the works of Descartes were written in Holland. From 1630-32, and again from 1633-34, he lived in Amsterdam. Amsterdam was the London of that time in many ways. Another Frenchman who lived there in the 17th century described Amsterdam as "the most beautiful city of Europe." And Descartes evidently enjoyed his life there. In one of his letters to Balzac, dated Amsterdam, May 15, 1631, Descartes expressed

his deep satisfaction with his life there, and some of his reasons for it

"In this great city where I now am," he wrote, "everybody but myself is in business and so engrossed with his profits that I could live here all my life without being noticed by anyone. I take my walk every day amid the Babel of a great thoroughfare with as much freedom and repose as you could find in your garden walks, and I observe the people whom I see just as I should the trees that you find in your forests or the animals that graze there, even the noise of their bustle does not disturb my reveries more than would the murmuring of a stream. When I consider their activities I derive the same pleasure which you have in watching the peasants till your fields, for I see that all their toil helps to adorn the place of my abode, and supplies all my wants. If there be pleasure in seeing the fruit grow in your orchard, think you there is not as much in seeing the vessels arrive which bring an abundance of all the produce of the Indies and all that is rare in Europe? What other place could you choose in all the world where all the comforts of life and all the curiosities that can be desired are so easy to find as here? What other country where you can enjoy such perfect liberty, where you can sleep with more security, where there are always armies afoot for our protection, where poisoning, treacheries, calumnies are less known, and where there has survived more of the innocence of our forefathers?"

In 1632 Descartes moved to Deventer. Here apparently he met a certain Hélène who, in 1635, bore him a child, which was christened Francine Descartes, and died at the age of five. It was during his stay in Deventer that Descartes heard of the Inquisition's condemnation of Galilei, in 1633, for supporting the Copernican hypothesis that the earth moves round the sun. Descartes had already written the greater part of a treatise, called *The World*, in which the Copernican hypothesis had been adopted. He at once abandoned the idea of completing and publishing the book, in the hope of discovering some more orthodox form of Copernicanism. Thus he eventually discovered in his vortex theory. Part of 1633 and 1634 was spent in Amsterdam. Descartes then moved to Utrecht in order to be near his first disciple, Renier, who was professor at the university there.

From Utrecht Descartes went to Leyden, where he lived during 1636 and 1637, and again in 1640 and 1641. It was during his first stay here that he published, in 1636, the volume of essays containing the *Discourse on Method*, the *Dioptrics*, *Meteors* and *Geometry*, and during his second stay here he published, in 1641, his *Meditations on First Philosophy*, together with *Objections* by Arnauld, Gassendi, Hobbes and others, and his *Replies* to them. From 1637-40 Descartes lived at Santpoort. After his second residence at Leyden he moved, in 1641, to Endgeest, near Leyden, where he remained till 1643. Here, in 1642, he was visited by Sorbière, the French courtier, traveller and gossip, whose *Voyage to England* subsequently caused so much annoyance to the Royal Society of London. And we are indebted to Sorbière for an interesting sketch of Descartes' life and surroundings at Endgeest. This is what he has written: "I was delighted with the civility of this gentleman, his retreat, and his household. He lived in a small château, beautifully situated, near a great and fine university (Leiden), three leagues from the court, and hardly two hours from the sea. He had a sufficient staff of servants all well chosen and comely people, a nice garden with an orchard beyond it, and all around there were pastures from which stood out many steeples of various heights, until in the far horizon they appeared as mere points. He could go in a day by canal to Utrecht, Delft, Rotterdam, Dordrecht, Haarlem or Amsterdam. He could spend half his day at The Hague and return in the evening, making this excursion by the most beautiful road in the world through meadows and houses of pleasure, then through a great wood bordering this village which is not inferior to the forest towns of Europe, and boasted at that time the residence of three courts. That of the prince of Orange was quite military. That of the States General was composed of deputies from the united provinces and of burghmasters. The court of the queen of Bohemia, widow of King Frederick V., the elector palatine, might be compared to that of the Graces, where all the fashionable world of The Hague

went almost daily, to pay their homage to the talent, virtue and beauty of her four princesses, the eldest of whom (Elizabeth) had a fancy for the discourse of M. Descartes."

In the meantime Descartes was having his share of trouble too. His leading ideas were known to various scholars several years before they were published in book-form. Already in 1634 some of his doctrines were taught in the university of Utrecht by Renier. It was in order to help Renier in this work that Descartes had removed to Utrecht in 1635. The publication of the *Discourse*, etc., in 1636 soon involved Descartes in numerous controversies with mathematicians in Belgium, Holland and France, notably with Fermat. And for the rest of his life Descartes was frequently involved in controversies which sometimes embittered him, and which probably had something to do with his decision to go to Stockholm in 1649. Perhaps the most unpleasant of these controversies was that with G. Voetius, a Protestant divine and zealot, and rector of the university of Utrecht. When Renier died in 1639 the funeral oration delivered by Emilius, lauded the dead scholar's friendship with Descartes, and incidentally Descartes himself. Voetius, a protagonist of ancient philosophy as allied with his theology, became alarmed and took an early opportunity to hunt at the atheism of the new philosophy. In 1641 Regius, another Utrecht professor who for a time was an enthusiastic follower of Descartes, openly advocated certain Cartesian theses which so alarmed Voetius that he persuaded the magistrates of Utrecht, as well as the university, to pass judgment in favour of the old philosophy against the new. In 1642 Descartes brought out the second edition of his *Meditations*, with an introductory *Lettre au P. Dinet*, containing an attack on Voetius, who was so furious that he not only complained again to the magistrates, but also instigated the publication of a violent attack on Descartes in a pamphlet entitled *Admiranda Methodus sive Philosophia Cartesianae*, ostensibly written by M. Schoeck, who subsequently disowned it. Descartes replied in *Epistola ad Celeberrimum Virum Gisbertum Voetium* (May 1643). Thereupon the magistrates of Utrecht summoned Descartes to appear before them. Descartes did not appear, but sent them a letter. He was summoned a second time, and judgment was passed against him by default. Thanks to the intervention of influential friends at The Hague, the matter went no farther. The Utrecht magistrates simply decreed, in 1645, that nothing should be published either for or against the new philosophy. Descartes was also attacked by some of the professors at Leyden. And to crown it all he was soon involved also in a quarrel with Regius, whose aggressive advocacy of Cartesianism (as he understood or misunderstood it) had been the chief cause of the trouble with Voetius. The results of this quarrel were a *Programma* by Regius, and a reply by Descartes, *Notae in Programma*, in 1647.

However, if Descartes had some enemies in Holland among people like Gisbert Voetius, he also had many friends and admirers, and among these was the Princess Elizabeth to whom Sorbière referred in the passage cited above. As has already been mentioned above, Frederick V., the father of Elizabeth, had met with disaster at the battle of Prague (Nov. 1620). He lost the crown of Bohemia, and fled to the Netherlands. He was then in the Netherlands, and it was of great interest, as also subsequently his *Meditations* (1641), and made his personal acquaintance about 1640. Descartes dedicated to her his *Principles of Philosophy*, in 1644, and the dedicatory letter which he addressed to her shows what a deep impression she had made on him.

"The greatest advantage (Descartes wrote) I have derived

from my writings is the honour of becoming acquainted with your highness, and of being permitted at times to converse with you, and thus becoming a witness of your rare and estimable qualities, and I am sure that I shall render a service to posterity by holding them up as an example. It would be foolish of me to flatter, or to state what I am not convinced of, on the first page of a book in which I seek to expound the fundamental principles of knowledge.

I have met no one who has such a thorough and comprehensive understanding of my writings as you have. Even among the best and most cultivated minds, there are many who find them very obscure, and nearly always those who are familiar with mathematics cannot comprehend metaphysics, while those conversant with metaphysics cannot understand mathematics. The only mind, as far as my experience goes, to which both alike are easy, is yours, and so I am compelled to regard it as incomparable. And what increases my admiration is that it is not an aged man, who has given many years to study, in whom such wide and scientific knowledge is found, but a young princess whose charms resemble the Graces, as the poets describe them, rather than the Muses or the wise Minerva. I see in your highness all those excellences that are requisite to pure and sublime wisdom on the part, not only of the mind, but of the will and character, magnanimity and gentleness are united with a disposition which an unjust fortune with its persistent persecutions has not been able to embitter or discourage. It is this high-minded wisdom that I reverence in you, and I dedicate to it not only this work, because it treats of philosophy or the study of wisdom, but myself and my services." Apparently Descartes met the Princess Elizabeth fairly frequently during the years 1641 till 1643 when they lived near one another, but they do not seem to have met again after Elizabeth left The Hague in that year, though various letters passed between them almost to the time of his death, including one letter in which he consoled with her on the execution of her uncle, Charles I. Elizabeth lived for a time in Berlin, then in Heidelberg with her brother, and eventually she became abbess of the abbey of Herford (in Westphalia), where she died on the 30th anniversary of the death of Descartes (Feb. 11, 1680).

Descartes left Endgense in 1643, and lived at Edmond-op den-Hoeft till 1644. His next, and last, place of residence in Holland was at Edmond-Binnen, near Alkmaar. Here he wrote his *Treatise on the Passions of the Soul* in 1649.

During the 21 years that Descartes lived in Holland (1628-49) he visited France on only three occasions, namely, in 1644, 1647 and 1648. The last of these visits was in connection with a royal pension, and in the hope of securing a congenial and important post in Paris. But he arrived in Paris at an unpropitious moment. It was on the eve of the civil war (the Fronde). So he hurried back to Holland empty handed.

In the meantime Chanut, the French resident at Stockholm, was trying to interest Christina, the queen of Sweden, in the philosophy of Descartes. Some correspondence followed, and in Feb. 1649, Descartes was invited to Stockholm. After his experience of royal patronage in Paris the year before, Descartes held back. A Swedish admiral was then sent to fetch him. But he hesitated still. Finally, however, he left Holland in Sept. 1649 for the Swedish court. Queen Christina received him in two audiences. He figured in various court functions, which did not

concern to him, and he regretted he had left Holland. He continued to work on his philosophy, and in April 1650 he wrote his *Principles of Philosophy*. He died on Feb. 23, 1650, at Stockholm.

THE PHILOSOPHY OF DESCARTES

Methodology.—In his *Principles of Philosophy* Descartes is interested in the problem of method—the determination of the right method for obtaining real knowledge by the natural light of reason. Like numerous thinkers before him Descartes was thoroughly dissatisfied with the method of scholasticism then still in vogue

The scholastic method, on which Descartes had been nurtured at La Fleche, consisted mainly in attempting to solve problems by citing the views of more or less eminent writers or "authorities," instead of dealing with the problems themselves. It called for much book-learning, as well as much ingenuity in reconciling or harmonizing conflicting authorities, but it did not encourage independent research or thought. Now Descartes was not a book worm by nature, and his early acquired habit of spending much time in bed was also more conducive to thinking than to much reading. Moreover, his genius was essentially mathematical, and in mathematics the question of "authority" did not arise even at his Jesuit school, where it counted in most other studies. Accordingly, we find Descartes engaged in questions of method already at an early stage in his career, and returning to them again and again subsequently. They are dealt with in his unfinished *Rules for the Direction of the Mind* (1628), in his fragmentary dialogue *The Search after Truth* (probably written either in 1628 or in 1641), in his *Discourse on the Method of Rightly Conducting the Reason* (published in 1637), in his *Meditations on First Philosophy* (published in 1641), and in *The Principles of Philosophy* (published in 1644).

In his autobiographical *Discourse*, Descartes relates how his dissatisfaction with book learning came upon him. "I have been nourished on letters since my childhood, and since I was given to believe that by their means a clear and certain knowledge could be obtained of all that is useful in life, I had an extreme desire to acquire instruction. But so soon as I had achieved the entire course of study, at the close of which one is usually received into the ranks of the learned, I entirely changed my opinion. For I found myself embarrassed with so many doubts and errors that it seemed to me that the effort to instruct myself had no effect other than the increasing discovery of my own ignorance. And yet I was studying at one of the most celebrated schools in Europe. I learned there all that others learned. And I did not feel that I was esteemed inferior to my fellow-students."

And this made me take the liberty of judging all others by myself and of coming to the conclusion that there was no learning in the world such as I was formerly led to believe it to be. And in his *Rules* he promptly demands that the investigation of any problem should not be dominated by what others have thought about, but by what we ourselves can see clearly or infer with certainty. "For" (he explains) "we shall not, for instance, become mathematicians, even if we know by heart all the proofs that others have elaborated, unless we have an intellectual talent that fits us to resolve difficulties of that kind. Neither, though we have mastered all the arguments of Plato and Aristotle, if we have not the capacity for forming a solid judgment on these matters, shall we become philosophers."

The one study which gave him real satisfaction was mathematics, "because of the certainty of its demonstrations and the evidence of its reasoning." He felt that there must be something about mathematics which made it a model for other studies. And he recalled with some satisfaction that "the earliest pioneers of philosophy in bygone ages refused to admit to the study of wisdom anyone who was not versed in mathematics, evidently believing that this was the easiest and most indispensable mental exercise and preparation for laying hold of other more important sciences." Now Descartes did not exaggerate the importance of mathematics after the manner of Pythagoras, as did even some of the most eminent astronomers of the 16th and 17th centuries. On the contrary, he speaks rather contemptuously of pure mathematics as such, remarking that "there is nothing more futile than to busy one's self with bare numbers and imaginary figures in such a way as to appear to rest content with such trifles." It was only the *method* of mathematics that appealed to him. And gradually the conviction grew on him that the method of mathematics could be extended to other sciences. Reference has already been made above to his experience on Nov. 10, 1619, for which he went on a pilgrimage to our Lady of Loretto. In course of time he formed the idea of "a species of mathematics," or a kind of "universal mathematics," that shall be applicable to all kinds of investigations. What he was thinking of was what may be called a Meth-

odology, or a study of scientific method, calling it a "species of mathematics" simply because "mathematics" literally means science. Methodical procedure in research was regarded by Descartes as of first rate importance. Random search for knowledge and trust in some chance luck he condemned as at once fruitless and intellectually demoralizing.

Now the method of mathematics consists in beginning with the simplest notions and then proceeding cautiously to deduce inferences from them. Similarly in all scientific investigations one should begin with the simplest and surest notions, and advance logically to more complex truths by a progressive synthesis of the simpler factors, that is, by deduction. Descartes realized, of course that knowledge is derived from experience as well as from deduction. But, in striking contrast with Bacon (whose *Novum Organum* he praised and commended to those who wished to follow the empirical path), he put more faith in deduction than in experience. Experience begins with very complex objects, and so our inferences from it are frequently fallacious, whereas deduction, according to Descartes, cannot be erroneous if carried out with moderate understanding. "This" (he says) "furnishes us with an evident explanation of the great superiority in certitude of arithmetic and geometry to other sciences. The former alone deal with an object so pure and uncomplicated, that they need make no assumptions at all which experience renders uncertain, but wholly consist in the rational deduction of consequences." The moral he draws is that "in our search for the direct road towards truth, we should busy ourselves with no object about which we cannot attain a certitude equal to that of the demonstrations of arithmetic and geometry."

The first problem of method turns on the starting-point, the simple notions or principles which furnish the material for the subsequent deduction. If the initial premises are false even the soundest deduction cannot lead to knowledge. How then do we come by our simplest notions or principles? "The first principles," says Descartes, "are given by intuition alone." And by intuition he means "the undoubting conception of an unclouded and attentive mind, which springs from the light of reason." Such intuitions are not uncommon. "Thus each individual can have intuition of the fact that he exists, and that he thinks, that a triangle is bounded by three lines only, a sphere by a single superficies, and so on. Facts of such a kind are far more numerous than many people think who disdain to direct their attention to such simple matters." Intuition and deduction, then, "are the most certain routes to knowledge." If any complex problem presents itself, the proper course is to analyse it into its simplest elements or notions, enumerate these carefully (this enumeration Descartes calls *induction*), make sure of each of them by intuition, and reason from them by deduction.

In the *Rules* Descartes made no attempt to get behind intuition as described and exemplified above. The *Discourse on Method*, however, is much more sophisticated. It begins with a methodical doubt which is intended to serve as a severe test for whatever may claim to serve as the sure starting-point of knowledge. Everything must be questioned (*de omnibus dubitandum*) so that we may discover something that is beyond doubt. At first everything seems to succumb to it—traditional beliefs, commonly accepted ideas, the very facts of direct observation may all be but illusions and dreams. Eventually, however, something is discovered that is beyond cavil; namely, doubt itself. He who doubts cannot doubt the reality of his doubting. But what is doubt? It is an act of thinking. And thinking implies a thinker. And so, says Descartes triumphantly, *Cogito, ergo sum*—"I think, therefore, I am." This, then, is an ultimate certainty. But why is it accepted as certain? Because it is so clearly and distinctly realized—it is an ultimate intuition that cannot be denied. This, however, implies that whatever is apprehended as clearly and distinctly is true. In this way Descartes found a philosophical basis for the acceptance of intuitions, and deduction from intuitions must at each step be as clearly and distinctly apprehended as the initial intuitions, though the connection between the final stage of a series of deductions and the initial intuitions may be a matter of memory rather than of immediate apprehension. Among the

ultimate intuitions Descartes evidently included the principle of universal causation, otherwise he could never have passed from *Cogito, ergo sum* to the existence of God, and from the existence of God to the reality of things that are clearly and distinctly apprehended. But these questions pertain to his metaphysics.

Metaphysics—Descartes once compared himself to Archimedes. This Greek founder of mechanics had said that if he could only find a fixed point in space to serve as a fulcrum for a suitable lever, he could lift the whole earth. Similarly, Descartes, in his stage of methodical doubt, said that if he could only discover something undoubtable he would rear on it a whole system of real science. And, as was explained above, Descartes found the required bedrock in the activity of doubt itself, in thought—*Cogito, ergo sum*. By "thought" he meant not only what is commonly meant by that term (the reflective solution of difficulties), but almost every kind of mental experience. "By the word thought I understand all that of which we are conscious as operating in us. And that is why not only understanding, willing, imagining, but also feeling are here the same thing as thought." But, even if we substitute the term "consciousness" for Descartes' "thought," what exactly is the extent of the knowledge furnished by the certainty that "I think"? It seems to be extremely limited, and to amount to no more than "I think" or "I am a thinking (or conscious) being," or "I experience certain mental processes or ideas." It does not warrant the reality of the apparently material objects of our perceptions, it does not prove the reality even of the body of the thinker. For in dreams such experiences occur although admittedly there are no such material objects corresponding to them. And, adds Descartes, "the same thing, perhaps, might occur if I had not a body at all." If so, thought might be a purely subjective matter, and throw no light at all on the question of the reality of an external world. There would be little comfort in the certainty that "I think, therefore I am" if the world of which I am conscious is but my dream-world, and "I" am but a solitary dreamer. It seems evident that Descartes' line of thought might end in so-called subjective idealism, or even in solipsism. It would be no great exaggeration to say that modern idealism and solipsism are the direct offspring of Descartes' thought. This, no doubt, may be regarded as a measure of his influence on modern philosophy, it may also be regarded as a measure of the mischief which he has wrought. Descartes did not consider sufficiently the claims of our waking consciousness to a direct apprehension of real external objects, his argument about dreams is not convincing, for, after all, it is easy enough to distinguish between dreaming and waking consciousness, and people are sometimes mistaken about what they think that they really think. He was probably betrayed partly by a bias common among mathematicians from the days of Pythagoras and Plato onwards, and partly by the early Christian tendency (under Platonic and Neo-Platonic influence) to belittle the material world. The former was probably the more important influence. Mathematicians as a class are so preoccupied with ideal or mental constructions that they are apt to exaggerate the powers of pure thought. Descartes clearly betrays this tendency already at the very beginning of his *Rules for the Direction of the Mind*, where he speaks of knowledge as though it were a kind of illumination which streams forth from the mind in the same way, without regard to differences in the objects studied. "The sciences," he says, "are identical with human wisdom, which always remains one and the same, however applied to different subjects, and suffers no more differentiation proceeding from them than the light of the sun experiences from the variety of the things which it illumines."

Descartes himself, however, was not a solipsist or even an idealist, his religion and his science saved him from that. He had, therefore, to bridge the gulf between the mere *cogito* and the external world. This he endeavoured to do by making his "I think, therefore I am" an argument for the existence of God, and then making God's being the ground for his belief in the existence of an external world. Descartes offers three proofs for the existence of God, one of them is *a priori*, based on the implication of the very notion of God, the others are *a posteriori* and argue from effect to cause. The *a priori*, or ontological proof, adapted more

or less from St Anselm, and most in accordance with Descartes' mathematical method, runs as follows "When the mind considers the diverse conceptions which it has, it discovers the idea of a Being who is omniscient, omnipotent and absolutely perfect, which is far the most important of all, and in this idea it recognizes not merely a possible and contingent existence, as in all the other ideas it has of things which it clearly perceives, but one which is absolutely necessary and eternal. For just as when it perceives that it is necessarily involved in the idea of a triangle that it should have three angles equal to two right angles, it is absolutely persuaded that a triangle really has three angles equal to two right angles, so from the fact it perceives that necessary and eternal existence is comprised in the idea of an absolutely perfect Being, it must clearly conclude that this absolutely perfect Being exists." Of the *a posteriori* proofs the more important one is the so called anthropological one based, not on the mere implication of the concept God, but on the existence of the idea in an existing but imperfect mind or minds. Descartes formulates it as follows "As we find in ourselves the idea of a God, or a supremely perfect Being, we can investigate the cause which produces this idea in us. But considering the immensity of the perfection it possesses, we are constrained to admit that it can only emanate from an all perfect Being, that is, from God who really exists. For it is not only made manifest by the natural light that nothing cannot be the cause of anything whatever, and that the more perfect cannot proceed from the less perfect as its efficient and total cause, but also that it is impossible for us to have any idea of anything whatever, if there is not within us or outside us an original which actually possesses all the perfections. But as we do not in any way possess all these absolute perfections of which we have the idea, we must conclude that they reside in some other nature different from ours, that is, in God." The other *a posteriori* argument infers the existence of God from the thinker's own existence, and his continued existence. These imply a Creator who has not only created the thinker, but maintains him in existence. For existence at one moment is itself no reason for existence at a subsequent moment, so that the conservation of whatever exists is really a continued creation.

The combined effect of all these arguments, taken in conjunction with his doctrine of innate ideas, of which the idea of God is one, may have been to give Descartes the conviction that he had in some way a direct intuition of God revealing Himself to Descartes through his innate idea of Him. But Descartes does not make himself clear on this point.

Having proved the existence of God as the supremely perfect Being, Descartes argues in the next place that God would not deceive the thinking beings He has created. So our sense-perceptions cannot be mere illusions, and there must exist an external world of Beings which we apprehend in perception. In this way, whereas his predecessors were wont to prove the existence of God from the existence of the world, Descartes inferred the existence of the world from the existence of God. But now he seems to have proved too much. Undoubtedly there are such experiences as illusions and errors. How shall we distinguish the real from the illusory? Descartes meets the difficulty by reverting to one of the main points in his methodology—we can only be sure of what we apprehend clearly and distinctly. Error is the result of the neglect of this precaution. It arises when our will goes beyond our understanding, as it often does. For our will has no limits, whereas our understanding is severely limited. And judgment, according to Descartes, is a decision of the will.

Clear and distinct apprehension must also be our guide in determining what these external material things essentially are. The sense-qualities, the so-called secondary qualities of things, such as colour, smell, etc., are not clearly and distinctly thinkable. Extension in three dimensions, and motion are the only features of material bodies that are clear and distinct to thought, and so they alone are the real essential features of material things, the so-called secondary qualities being but the subjective experiences of the percipient. In this way Descartes helped to lay the foundations of a mechanical interpretation of physical Nature. On the other hand the essential feature of minds is thought or conscious-

ness. Minds are essentially thinking substances, just as bodies are essentially extended substances. For Descartes, accordingly, Reality consists of God, the perfect Being and Creator, and His Creations, namely, thinking substances, or minds, and extended substances, or bodies. And, prompted by his religious training, Descartes endeavours to set bodies and minds in extreme opposition to one another—whatever mind is, body is not. One result of this is that because mind is active, body is not, and so he conceives of motion, not as a property of bodies, but as something put into them by God. Another result is that there can be no interconnection between body and soul. Lower animals are consequently conceived by Descartes as mere automata, cleverly constructed mechanisms without soul. And the undeniable conjunction and apparent interaction of mind and body in human beings is in the last resort explained by the constant intervention of God.

The philosophy of Descartes has undoubtedly exercised a potent influence on modern thought, and to that extent the usual designation of Descartes as the father of modern philosophy is justified. But the intrinsic merits of his philosophy have been grossly exaggerated, and the exaggeration is itself due to a misinterpretation of Descartes' mentality. Descartes was a dual personality. Two tendencies struggled within him. On the one hand, there was the mathematical genius with a passion for clear and distinct ideas, and for logical deduction. On the other hand, there was the loyal Catholic, genuinely attached to a certain traditional theology. So long as he pursued problems of a purely scientific character, especially problems pertaining to pure or applied mathematics, he was in his element and showed his master mind. But the moment he attacked problems of general philosophic orientation, he was the traditional theologian rather than the revolutionary philosopher. Historians of philosophy have tried to save the philosophic reputation of Descartes by treating his theology as mere camouflage. But that is a mistake. Mersenne had a keen scent for heresy, yet he defended Descartes' orthodoxy, and Mersenne was well informed about Descartes. It is not very unusual even in the 20th century, it was certainly not unusual in the 17th century, for the same person to be a detached scientist when dealing with one set of problems, and a conservative theologian when dealing with another set of problems. And Descartes was of that type. In the same breath with which he asserted that the mind should admit no other methods than intuition and deduction, he also asserted "but this does not prevent us from believing matters that have been divinely revealed as being more certain than our surest knowledge, since belief in these things is an act, not of our intelligence, but of our will." His abandonment of the idea of the earth's motion and his substitution of the vortex theory was probably due to his genuine regard for the authority of the Catholic Church, not to fear. Saumaise, who visited Descartes at Leyden in 1637, reports that he was a Catholic "des plus zélés." His whole orientation was essentially that of popular Christian theology, with its supernatural God, who created souls and bodies. And when he went the length of regarding distinctions between good and evil, between truth and falsehood as depending on the arbitrary decisions of the Divine Will, he really abandoned altogether the realm of rational philosophy for that of a particularly narrow mediaeval theology. Descartes' methodical doubt has misled people into supposing that he was a revolutionary philosopher. But in the history of human thought real "believers" have posed as sceptics almost as often as real sceptics have posed as believers.

DESCARTES' CONTRIBUTIONS TO SCIENCE

From what has already been said above about Descartes' Methodology, one almost expects that his endeavour would be to reduce all science to a kind of applied mathematics. And that is what he really did attempt. "I do not accept or desire," he wrote, "any other principle in physics than in geometry or abstract mathematics, because all the phenomena of nature may be explained by their means." Another way of expressing the same thing is to say that Descartes tried to reduce every science of natural phenomena to a branch of mechanics. But it must be remembered that for Descartes mechanics was essentially kinetics, not dynamics—a

calculus of changes of position, not a calculus of "forces" The progress of the physical sciences during the 17th and 18th centuries was due in large measure to the adoption of a mechanical interpretation of physical phenomena This method of interpretation was initiated by Galileo and extended by Descartes Its merits can only be appreciated when one recalls the "substantial forms," "hypostatical principles," "real accidents," and other mystifying conceptions of the pseudo-science which preceded the Cartesian attempt to interpret all natural phenomena by means of clear and distinct mechanical concepts It was left to a later age to discover the inadequacy of an exclusively mechanical interpretation of natural phenomena But this must not be allowed to detract from the merits of Descartes in the history of science

Physics and Cosmology—Descartes, by refusing to attribute to matter any sense qualities, which are not reducible to clear and distinct ideas, reduced matter to extension in three dimensions Matter thus coincided for him with space One consequence of this was that he denied the existence of a vacuum For the same reason he also rejected the existence of "atoms" in the literal sense of the term, for any minute part of space or extension remains theoretically divisible But how does this apparently continuous extension come to assume the form of those detached material bodies with which we are familiar? Descartes explains this by reference to motion, which he regards as a separate creation of God, who also conserves its quantity It is motion that leads us to distinguish separate bodies or parcels of matter Any part of extension that moves together or simultaneously is regarded as such a body Since, however, matter is extension and there is no vacuum, the motion of one body must be followed immediately by the motion of certain other bodies, so that the circle of extension may remain complete, without gaps This idea of a circular motion of matter eventually suggested to him his theory of vortices "All natural motions" (Descartes explains in *Le Monde*) "are in some way circular When a body leaves its place, it enters that of another, and this enters that of yet another, and so on to the final one which occupies at the same instant the place left by the first There is thus no vacuum between bodies when they move, any more than when they are at rest To this end it is not at all necessary that all the moving parts should be arranged in a true circle, or be of like size or shape, for inequalities in these respects may be compensated for by other inequalities We do not commonly observe these circular motions in the air, because we are accustomed to regard the air as an empty place But if we observe fishes swimming in a basin we see that, if they do not approach too near it, they do not stir the surface, although they pass under it at a great speed It is clear, therefore, that the water which they push before them does not push indifferently all the water in the basin, but only that which can best serve to complete the circle of their motion and enter the place which they have vacated"

Another consequence of Descartes' identification of matter with extension or space was his insistence on the unity of physical nature, which must be a *universe* because space is one and continuous Both in his early work *The World* and in his *Principles of Philosophy*, Descartes attempted to give an account of the genesis or formation of the physical world The account was intended to be purely hypothetical or speculative, not a rival theory to *Genesis*—just a flight of fancy based on Cartesian principles "Give me extension and motion," he said in his earlier book, "and I will construct the world" Assuming that God has created a uniform matter (or extension) and endowed it with a fixed quantity of motion, which follows certain laws (namely, the laws of motion formulated by Descartes), how might a world (like the existing world) have come into being "by natural and gradual means"? Descartes answers the question somewhat as follows

In a world closely packed with matter so that there is no vacuum in it the only kind of motion possible is that described above as circular motion or vortex (whirlpool) motion Consequently when motion was imparted (by God) to matter, such vortices were set in motion—innumerable more or less circular eddies of material parts of all sorts of shapes, sizes and velocities The friction set up by this vortex motion of closely packed material bodies

results in the mutual rubbing off of their corners And so we get, to begin with, two main kinds of material particles—the original particles rendered smooth and globular by the friction which rubbed their corners off, and the inner particles composed of the rubbings or filings These fine particles Descartes calls "first matter", the larger, globular particles he calls "second matter" There is yet a "third matter," namely, the most massive and heavy of the original particles that suffer no fracture or rubbing off in the vortex motion, and such other original particles as, thanks to their peculiar shapes, combined into larger, stronger combinations that similarly resisted all damage The first kind of matter the finest sort, tends towards the centre of each vortex, where it forms self luminous suns and fixed stars The second kind of matter, consisting of globular particles, tends to move away from the centre of the vortices in straight lines towards the circumference It constitutes the transparent heavens, and transmits the light of the radiating stars The third and grossest kind of matter is that of which the earth, the other planets, and the comets are composed—these are all opaque bodies

In the *Principles* Descartes explains the formation of the comets and planets in this way Sometimes as the smaller particles in a vortex pass through the interstices between the revolving globular particles, they get caught and become twisted and channelled, and when they finally reach the stellar matter at the centre of the vortex they form crusts or "sun spots" on it This may cause a diminution in the expansive force of the star, which is then caught up by a neighbouring vortex If the velocity of the crusted star is greater than that of the encroaching vortex, the star will soon pass out of that vortex into another, and continue to wander from vortex to vortex It is then known as a comet But if the crusted star has a velocity equal to that of some part of the encroaching vortex, it will stay there and continue to revolve in that vortex In that case it is known as a planet The planets of the solar system are the crusted stars and their several vortices that have been swept up by the vortex of the sun

The vortex theory enabled Descartes to reconcile Copernican with Biblical doctrine In *The World* Descartes had embraced the Copernican theory of the earth's motion round the sun The condemnation of Galileo, in 1633, made him drop the idea in the Copernican form But by supposing the earth to be carried in its vortex round the sun, Descartes believed that he left the earth at rest in its vortex, and so satisfied the dogma of a stationary earth, while he also satisfied the Copernican theory inasmuch as he represented the earth's vortex as circling round the sun

Descartes' *Principles* contains a detailed account of practically all the natural phenomena that had been investigated up to his time It contains, of course, many errors Even his fundamental laws of motion are mostly inaccurate But it was an amazing attempt to reduce all natural phenomena to one system composed of one ultimate kind of matter and governed by the same laws of motion One of its incidental results was the explanation of weight without recourse to gravitation Bodies tend to fall towards the earth, according to Descartes, because the particles of the second kind of matter which move round the earth push those bodies towards the earth, and so give them what we call their weight The popular conception of gravitation makes more or less an occult power of it Newton's intention was merely to describe certain tendencies to movement without any attempt to explain them at all Again, Descartes' rejection of the existence of a vacuum not only undermined the idea of Nature's abhorrence of a vacuum (*horror vacui*) which was wont to serve as an explanation of the action of water pumps, but prepared the way to the correct explanation, namely the pressure of the air on the surface of the water In fact Descartes claimed that he had anticipated Torricelli (the inventor of the barometer) and that, during his visit to Paris in 1647, he had suggested to Pascal the idea of the barometric experiment which the latter carried out on the Puy de-Dôme on Sept. 19, 1648 Another important consequence of Descartes' rejection of a vacuum was that he was thereby led to give up the old corpuscular or emission theory of light, and to conceive of the transmission of light as a transmission of pressure from the luminous body through the intervening particles of secondary

matter to the sensitive eye. This view prepared the way for the undulatory theory of light which was soon afterwards formulated by Christiaan Huygens, the son of Descartes' friend and correspondent, Constantijn Huygens.

Descartes was deeply interested in optics, devoting to it not only his *Dioptrics* (1636), but also parts 3 and 4 of his *Principles* (1644). He compares the transmission of light to the eye with the way in which a blind man feels his way with a stick. The resistances or pressures of the different objects (such as stones, trees, water, etc.) are transmitted along the stick to his hand and thence to his brain, so that he can distinguish them. Similarly no corpuscles actually pass from the visible objects to the eye, only a pressure through the fine particles which constitute the transparent medium. Rays of light are the line along which the pressure is transmitted. When they pass through a transparent medium they are straight, otherwise they are deflected or even stopped just like a moving ball when it encounters some obstruction. If the obstruction is hard, the ball rebounds in another direction; if soft, its movement will be arrested. Similarly, when a ray of light impinges obliquely on certain kinds of surfaces, it is reflected, and its angle of reflection is equal to the angle of incidence. But if the medium allows the ray to pass through with diminished speed, then it is refracted. In the *Dioptrics* the law of refraction was published for the first time. Snell had discovered it in 1621, but did not publish it, and Descartes has sometimes been suspected of plagiarism. Most likely, however, Descartes discovered it independently.

Physiology—*The World*, as originally planned by Descartes, was to have contained an hypothetical account of the development of the universe from chaos to man. Referring to this book, in June 1633, he said: "I shall treat of man to a greater extent than I proposed, I intend to explain the principal functions of his body, and I have already given an account of some of them, such as digestion, the beating of the pulse, the distribution of nutritious matter, the action of the five senses, etc. I have dissected the heads of various animals, in order to ascertain in what memory, imagination, etc., consist." The book was not published as it was then planned, but the results of Descartes' studies in this field are contained in his *L'Homme* (published in 1662), the first text book on physiology. In accordance with the whole spirit of *The World*, of which the treatise on *Man* was originally meant to be the concluding part, the human body and its functions were treated by Descartes mechanically, like "an earthly machine." In this view he was greatly encouraged by the views of Vesalius (1515-64), the father of modern anatomy and physiology, and by Harvey's demonstration of the mechanical nature of the circulation of the blood (his *Exercitatio* was published in 1628), though Descartes did not entirely agree with Harvey. Descartes explains that blood is formed in the liver from the chyle of the food. This blood flows drop by drop into the right cavity of the heart, which is so hot that the blood expands and is exhaled into the lung, whence it passes into the left cavity of the heart, and is thence distributed over the whole body. He describes the valves in the arteries which secure that the blood shall flow only drop by drop. Now of the blood which flows through the direct arteries from the heart to the brain, "the most agitated and vivified parts" are called "animal spirits." They are like "a very subtle air." By dilating the brain they enable it to receive impressions of external objects, and so give rise to sensation, imagination and retentive memory, by flowing from the brain through the nerves into the muscles, they enable the nerves to function as organs of the external senses, and by distending, and so contracting, the muscles, they effect the movements of the limbs. For Descartes the "animal spirits" were just a subtle fluid, the nerves were just tubes through which they flowed in a mechanical way.

He illustrates his strictly mechanical conception of the bodily machine as follows: "You may have seen in the grottoes and fountains which are in our royal gardens that the simple force with which the water moves when issuing from its source is enough to set in motion various machines, and to make various instruments play or utter words, according to the different arrangements of the tubes which convey the water. And so one may well

compare the nerves of the machine which I am describing with the tubes of the machines of these fountains, the muscles and tendons with the other engines and springs which move the machines, and the animal spirits, the source of which is the heart, and of which the cavities of the brain are the reservoirs, with the water which puts them in motion. Moreover, breathing and similar acts, which are natural and usual to the machine, and which depend on the flow of the spirits, are like the movements of a [water] clock or of a mill which the ordinary flow of water keeps going continually. External objects, which by their presence act on the sense organs of the machine and so determine it to move in different ways according to the disposition of the parts of the brain, may be compared to strangers who, entering one of the grottoes containing many fountains, themselves cause unwittingly the movements they witness. For on entering they tread on certain tiles or plates which are so arranged that if they approach a bathing Diana they cause her to hide in the rose bushes, and if they try to follow her they cause a Neptune to come towards them threatening them with his trident. Or if they pass in another direction they make a sea monster spring forward and spout water in their faces, or things of a like kind according to the caprice of the engineers who constructed them.

"In order to understand how the brain can be excited by external objects which affect the organs of sense, so that all the members can be moved in a thousand different ways, imagine that the delicate threads which arise from the inside of the brain and form the marrow of the nerves, are so disposed in all those parts which serve as the organs of any sense that they can be easily set in motion by the objects of the senses, and that whenever they are so set in motion, even ever so little, they pull upon the parts of the brain whence they originate, and so open certain pores on the internal surface of the brain. Through these pores the animal spirits in the ventricles pass into the nerves and then into the muscles which carry out movements like those to which we are incited when our senses are affected in that way. If, e.g., fire comes near the foot, the minute particles of the fire are set in motion the skin of the foot, and by thus pulling the delicate thread attached to the skin there, they open the pore against which the thread ends, just as by pulling at one end of a rope one rings a bell at the other end."

In this way Descartes tried to explain physiological phenomena mechanically, and to banish from biology such conceptions as those of "vegetative" and "sensitive" souls, much in the same way as he and Boyle, and others, tried to banish from physics and chemistry such notions as those of "substantial forms," and occult qualities, etc. To this extent he rendered a service to biology in spite of his excessive proneness to follow the high *a priori* road, and to be satisfied with any fancies that seemed "clear and distinct" to him. He may be credited to some extent with the anticipation of the conception of "reflex movements," though these are not interpreted now in his purely mechanical fashion. He may also be regarded as the forerunner of modern "behaviourism," at all events as applied to the lower animals, for he would certainly have condemned a "soulless" human psychology, as will be seen presently. His view of the lower animals as mere automata rather alarmed some people. But Descartes' main object was to vindicate the superiority of man over animals, even over his own animal body, in virtue of his "rational soul" or mind.

Body and Mind—In Descartes' philosophy, as already explained, the human mind is "a thinking substance" *totio coelo* different from any "extended substances," including human bodies. Yet a human being seems to be an intimate association of a mind and a body, each influencing the other. How can the "extended substance" or "earthly machine" of the human body come into such intimate relation with unextended "thinking substance"? Descartes' ultimate solution of these, as of all other problems, lies in God, who graciously does all that Descartes thinks ought to be done. But as a more immediate, scientific solution of the problem, Descartes suggests that the mind comes into contact with the body in the conarium "whence it radiates through the rest of the body by means of the animal spirits, nerves and even the blood." The pineal gland "in the middle of the substance of the

brain" is the primary reservoir of animal spirits, the central cavity of the brain being the secondary reservoir. Reverting to the above-mentioned comparison with the mechanical inventions in the royal gardens, Descartes likens the function of the rational soul or mind presiding at the conation to that of "the fountain which has to take his place in the reservoir whence all the different tubes of the machines proceed whenever he wants to start them, to stop them, or to change them in any way." Descartes thought he surmounted the difficulty of explaining the mutual influence of mind and body by supposing, on the one hand, that the conation requires but a minimum of influence to incline it one way or another, and, on the other hand, that the "animal spirits" are such a subtle kind of air that they are on the verge of ceasing to be material. But according to his own philosophy the material remains material however fine it may be, and so remains entirely alien from the mental or spiritual.

Psychology.—The mind being, according to Descartes, a thinking substance entirely different from, and independent of, extended or material things, it "can work independently of the brain." This, at all events, is true of the most characteristic activities of the rational soul, "for clearly there can be no use of the brain for pure intelligence," says Descartes. Ideas in which pure intelligence expresses itself are innate, not derived from without, but from the rational soul itself. For Descartes, as for Plato, experience can only be the occasion for the recall of such ideas to consciousness. These ideas are not always explicit in our consciousness, rather they are latent in the "thinking substance," but they are not originated by experience, though experience may occasion their explicit recall. Among such innate ideas Descartes includes our "clear and distinct" ideas of God, of the self as a thinking thing, the axioms of mathematics and other so-called "common notions" like those of space, time and motion. Above all, perhaps, he finds the mind expressing itself most fully in acts of will, under which heading he includes all judgments and beliefs, as well as voluntary decisions. But then the mind is conjoined with a body, and they do somehow influence each other through the mediation of the conation and the animal spirits, as already explained. One result of this is that in addition to the mind's own innate ideas, we have also "adventitious ideas" which come to us through the influence of external bodies, and also "fictitious ideas" of merely imaginary objects which the mind puts together out of simpler "adventitious" and "innate" ideas. Descartes is not very clear or consistent in dealing with these problems. The idea of God, e.g., is treated at once as "innate" and also as produced in us by God Himself and therefore, in a sense, "adventitious." And his treatment of images is rather bewildering. Sometimes he treats images, in contrast with ideas, as something physical, and says "no corporeal image is received in the mind, pure thinking is carried out without corporeal images, imagination, however, which can only arise in the case of corporeal things, needs an image, which is a truly corporeal thing, to thus the mind applies itself, though the image is not received into the mind." At other times, however, he includes images, and even sensations and perceptions, under "thought," and distinguishes them from innate ideas, or pure thoughts, and volitions in so far as "imagination and sensation" need the brain as well as the mind, that is to say, in so far as they express not the pure activity of mind, but rather its *passivity*, the effect upon it of physical things, including the body with which it is united. Hence he calls all such experiences "passions," under which heading he includes not only the feelings and emotions, but also sensation, reflection, perception, and all adventitious ideas. The feelings are passions caused by the agitation of the animal spirits, but are not referred to any objects outside the body, whereas sensations are "passions" that are referred to external stimuli. Descartes' account of the emotions anticipates to some extent the James-Lange theory, inasmuch as it gives primary to the physical or physiological processes. Our perception of certain animals, e.g., causes fear and flight immediately without the mediation of reason or volition, which only come into play afterwards. Since, however, the brain is the organ of the passions, and also the seat of the rational soul, the passions can be brought under the control of the reason and the will. In fact,

Descartes is quite Socratic in his insistence on the competence of right reason to conduce to right feeling and action.

The power which Descartes attributes to reason and will may seem to be little in harmony with his naturalistic, mechanical account of such large tracts of human experience. But, as already remarked, his great aim was really to vindicate the supremacy of the human mind or spirit. There was a marked tendency in his day, and long before him, to efface the sharp distinction between man and the lower animals by crediting the lower animals with human powers, including intelligence, which they were sometimes said to use more humanly than man. This tendency was mainly supported by the results of comparative anatomy, which showed essential similarity between the structures of human and animal bodies, including the central nervous system. Descartes tried to save the situation by regarding even the human body as a machine, and treating mechanically all such human experiences as might conceivably also be credited to lower animals, but claiming unique privileges for the rational soul, which he regarded as the *differentia* of man, and as absolutely independent of all that is material.

Mathematics.—Descartes has been described as the first modern mathematician. He was certainly one of the pioneers of modern mathematics. His only treatise on mathematics is the *Geometry* (1637) in which he laid the foundations of analytical or algebraic geometry. Descartes was not the first to apply algebra to geometry, or to conceive a line as generated by a moving point, or to solve geometrical problems by regarding them as solved and analysing the result ("analytic geometry" in the older sense). These things were already known to ancient and medieval mathematicians. But he applied these methods much more systematically and fruitfully.

He knew that a point in a plane can be fully determined if we know its distances from two given straight lines in the same plane (allowing for the sign-conventions relating to their different sides, and taking not perpendicular distances but distances parallel to given lines). If the distances be represented by x and y respectively, we can get an equation of the form $f(x, y) = 0$. And although such an equation is indeterminate in the sense that it can be satisfied by an infinite number of sets of values of x and y , yet these values determine the co-ordinates of a series of points which form a curve such that the equation in question is true of every point on it. He realized, moreover, that the properties of a curve can be ascertained by choosing as a definition any specific geometrical property, and expressing it as an equation by means of the co-ordinates of any point on the curve. Such an equation contains by implication all the properties of that curve. And any such property can be deduced from the equation by purely algebraic processes, and without direct reference to the geometry of the curve.

Descartes was the first to attempt a systematic classification of curves. First, he distinguished between "geometric" and "mechanical" curves, according as they could or could not be precisely expressed in equations. (These terms were subsequently displaced by Newton's terms "algebraic" and "transcendental.") Confining himself to "geometric" curves, Descartes classifies these into a series of classes of increasing complexity as follows. Class I consists of curves (the circle, the parabola, the hyperbola and the ellipse) whose equations contain no term of higher degree than the multiple of two unknown quantities or the square of one. Class II includes any curve whose equation contains one or more terms of the third or fourth degree in one or both of the two unknown quantities. Class III contains curves whose equations include a term of the fifth or sixth degree in either or both of the unknown quantities, and so on. The curves are paired in each class in the way indicated because there are methods of reducing a curve of the fourth to one of the third degree, a curve of the fifth to one of the fifth degree, and so on. The straight line he regarded as an exceptional case of a curve of the second degree (Class I).

In algebra Descartes's systematic application of it to geometrical mathematics involved important consequences. It involved the geometrical interpretation of negative quantities. It also led to the idea of continuity, which in its turn led to the theory of function

and to the theory of limits. Descartes, moreover, made important contributions to the theory of equations, to which the third and last book of his *Geometry* is devoted, and to which he appears to have been led by his (successful) efforts to solve the problems of doubling the cube and of trisecting an angle. It is also worth noting that we are indebted to Descartes for the convention of using the first letters of the alphabet to represent known quantities, and the last letters for unknown quantities. He also introduced our system of indices (although he frequently used x^2 instead of x^2). On the other hand, he used the sign ∞ instead of ∞ which Recorde had already introduced with its present meaning.

Descartes' general rule for solving equations is this: Write the equation in the zero form, and try to factorize the L.H.S. so as to reduce the equation to two or more equations of lower degree. If this is impossible, higher methods must be used. If the equation is of the third or fourth degree, the solution depends on the intersection of a circle with a conic. To solve equations of still higher degree, Descartes proposes the use of intersections of circles with the successive classes of geometric curves—conics being used to generate curves of Class II, and these again to generate curves of Class III, and so on. He thought that equations of any order could be solved in this way, but he was mistaken.

What is still known as Descartes' Rule of Signs is to the effect that an equation can have no more "true" (i.e., positive) roots than its coefficients have changes of sign from $+$ to $-$, and no more "false" (i.e., negative) roots than the number of times two plus or two minus signs occur in succession.

BIBLIOGRAPHY.—*Oeuvres de Descartes*, ed. by C. Adam and P. Tannery (11 vols., 4to, Paris, 1897-1912). This edition supersedes all other editions of Descartes' works. Since then some hitherto unpublished letters have been edited by L. Roth in *Correspondence of Descartes and Constantijn Huygens, 1625-47* (Oxford, 1926). The most reliable biography of Descartes is that by C. Adam, forming vol. xii of the above mentioned *Oeuvres de Descartes*. Of books for English readers the following are the most important: *The Philosophical Works of Descartes* rendered into English by E. S. Haldane and G. R. T. Ross (2 vols., 1911, 1912), Kuno Fischer, *Descartes and his School*, translated by N. Porter (1887), J. P. Mahaffy, *Descartes* (1902), E. S. Haldane, *Descartes, His Life and Times* (1905), N. Smith, *Studies in Cartesian Philosophy* (1902), L. Roth, *Spinoza, Descartes and Madamouze* (1924), *The Cambridge Modern History*, vol. iv, chap. 27, contains an account of "Descartes and Cartesianism" by E. Boutroux, *Science Progress* (No. 33, 1927) contains an account of "The Physical Work of Descartes" by F. Wootton, *The Geometry of Rene Descartes*, translated by D. E. Smith and M. L. Latham (1924), M. Foster's *History of Physiology* (1924) deals with Descartes' Physiology, and G. S. Brett's *History of Psychology* (vol. 1, 1921), treats of Descartes' Psychology. See also the *History of Philosophy* by J. E. Erdmann, H. Höfding and W. Windelband, and articles *CARTESIANS*, *PHILOSOPHY*, *HISTORY OF*, *PHYSIOLOGY*, *HISTORY OF*. The best German translation is that by A. Buchenau, *Descartes' Philosophische Werke* (Leipzig, 1905-11). Of German books on Descartes the following are the most important: A. Hoffmann, *Rene Descartes* (Frommann's Klassiker der Phil., Stuttgart, 1922), K. Jungmann, *R. Descartes* (Leipzig, 1908), A. Kastl, *Descartes* (Halle, 1909), E. v. Aster, *Einführung in die Phil. Descartes* (München, 1921), C. v. Brockdorff, *Descartes* (München, 1923), E. Cassirer, *Descartes' Kritik der mathem. u. naturw. Erkenntnis* (Marburg, 1896), and *Das Erkenntnisproblem* (vol. 1, book III, Berlin, 1911). P. Natorp, *Descartes' Erkenntnistheorie* (Marburg, 1882). Of recent French books the following may be mentioned: O. Hamelin, *Le Système de Descartes* (1911), G. Milhaud, *Descartes Savant* (1921), E. Gilson, *La Liberté chez Descartes et la Théologie* (1913), H. Gouhier, *La Pensée Religieuse de Descartes* (1924).

(A. Wo.)

DESCHAMPS, ÉMILE (1791-1871), French poet and man of letters, was born at Bourges. In 1814 he collaborated with Henri de Latouche in two verse comedies, *Silvain et de Florian* and *Le Tour de faveur*. He and his brother were among the most enthusiastic disciples of the *École gauthier* around Victor Hugo, and in July 1823 Emile founded with his brother the *Muse française*, which during the year of its existence was the special organ of the romantic party. His *Études françaises et étrangères* (1828) were preceded by a preface which may be regarded as one of the manifestos of the romanticists. The version of M. de la Harpe's *Roméo et Juliette* (1839) and *Wacchet* (1841), important as they were in the history of the romantic movement, were never staged. He was

the author of several libretti, among which may be mentioned the *Roméo et Juliette* of Berlioz. His works include two volumes of stories, *Contes physiologiques* (1854) and *Réalités fantastiques* (1854). He died at Versailles on April 23, 1871. His *Oeuvres complètes* were published in 1872-74 (6 vols.).

His brother, Antoine François Marie, known as ANTOINE DESCHAMPS, was born in Paris on March 12, 1800, and died at Passy on Oct. 29, 1866. Like his brother, he was an ardent romanticist, but his production was limited by a nervous disorder, which has left its mark on his melancholy work. He translated the *Drama Commedia* in 1829, and his poems, *Derrière Paroles* and *Résignation*, were republished with his brother's in 1847.

DESCHAMPS, EUSTACHE, called MOREL (1346?-1406?), French poet, was born at Vertus, Champagne. He studied at Reims, where he is said to have received some lessons in the art of versification from Guillaume de Machault, who is stated to have been his uncle. From Reims he proceeded c. 1360 to the University of Orleans to study law and the seven liberal arts. He entered the king's service as royal messenger c. 1367, and was sent on missions to Bohemia, Hungary and Moravia. In 1372 he was made *hussier d'armes* to Charles V. He received many other important offices, was *bailli* of Vlois, and afterwards of Senlis, squire to the Dauphin, and governor of Fismes. In 1380 his patron, Charles V, died, and in the same year the English burnt his house at Vertus. In his childhood he had been an eye-witness of the English invasion of 1358, he had been present at the siege of Reims and seen the march on Chartres, he had witnessed the signing of the treaty of Bretigny, he was now himself a victim of the English fury. His violent hatred of the English found vent in numerous appeals to carry the war into England, and in the famous prophecy that England would be destroyed so thoroughly that no one should be able to point to her ruins. His own misfortunes and the miseries of France embittered his temper. He complained continually of poverty, railed against women and lamented the woes of his country. His last years were spent on his *Mirour de mariage*, a satire of 13,000 lines against women, which contains some real comedy. The mother in law of French farce has her prototype in the *Mirour*.

The historical and patriotic poems of Deschamps are of much greater value. He does not, like Froissart, cast a glamour over the miserable wars of the time but gives a faithful picture of the anarchy of France, and inveighs ceaselessly against the heavy taxes, the vices of the clergy and especially against those who enrich themselves at the expense of the people. The terrible brillad with the refrain *Sà, de l'argent, sa, de l'argent* is typical of his work. Deschamps excelled in the use of the ballade and the chant royal. In ballade form he expressed his regret for the death of Du Guesclin, who seems to have been the only man except his patron, Charles V, for whom he ever felt any admiration. One of his ballades (No. 285) was sent with a copy of his works to Chaucer, whom he addresses with the words

Tu es d'amours meandans deux en Albne
Et de la Rose en la terre Anglieue

Deschamps was the author of an *Art poétique*, with the title of *L'art de dicter et de fere chansons, balades, virelles et rondeaux*. He lays immense stress on the harmony of verse, because, as was the fashion of his day, he practically took it for granted that all poetry was to be sung.

The work of Deschamps marks an important stage in the history of French poetry. With him and his contemporaries the long, formless narrations of the *trouvères* give place to complicated and cutting kinds of verse. He was perhaps by nature a moralist and a satirist rather than a poet, and the force and truth of his historical pictures gives him a unique place in 14th-century poetry. Raynaud fixes the date of his death in 1406, or at latest, 1407. Two years earlier he had been relieved of his charge as *bailli* of Senlis, his plain-spoken satires making him many enemies at court.

His *Oeuvres complètes* were edited (10 vols., 1878-1901) for the *Société des anciens textes français* by Queux de Saint-Hilaire and Gaston R.naud. The supplementary vol. 11 (1902) consists of an introduction on G. Raynaud. See also E. Hoepfner *Eustache Deschamps* (Strasbourg, 1904).

DESCHANEL, PAUL EUGENE LOUIS (1856-1922), French statesman, son of Émile Deschanel (1819-1904), professor at the Collège de France and senator, was born at Brussels, where his father was living in exile (1851-59), owing to his opposition to Napoleon III. Paul Deschanel studied law, and began his career as secretary to Deshayes de Marcere (1876), and to Jules Simon (1876-77). In Oct. 1885 he was elected deputy for Eure and Loire. He was one of the most notable orators of the Progressist Republican group. In Jan. 1896 he was elected vice-president of the chamber. In June 1898 he was elected president of the chamber, and was re-elected in 1901, but rejected in 1902. In 1904 and 1905 he supported the law on the separation of Church and State. After presiding over the commission of foreign and colonial affairs (1905-09) and acting as reporter of the foreign office estimates committee, Deschanel filled many responsible positions. In Jan. 1920, he was elected president of the Republic, as being a "safer" candidate than Clemenceau, though the latter's popularity spoke strongly in his favour. In the autumn of the same year, however, failing health obliged him to resign office. He died in Paris on April 28, 1922, from the effects of a fall from a railway carriage. Deschanel was elected a member of the French Academy in 1899, his most notable works being *Orateurs et hommes d'état* (1888), *Figures de femmes* (1899), *La Décentralisation* (1905), *La Question sociale* (1898).

DESCLOZITE, a rare mineral species consisting of basic lead and zinc vanadate, crystallizing in the orthorhombic system and isomorphous with olivenite. It occurs as small prismatic or pyramidal crystals, usually forming drusy crusts and stalactitic aggregates, also as fibrous encrusting masses with a mammillary surface. The colour is deep cherry red to brown or black, and the crystals are transparent or translucent with a greasy lustre, the streak is orange yellow to brown, specific gravity 5.9 to 6.2, hardness $3\frac{1}{2}$. A variety known as cuprodesclozite is dull green in colour, it contains a considerable amount of copper replacing zinc and some arsenic replacing vanadium. Desclozite occurs in veins of lead ores in association with pyromorphite, vanadinite, wulfenite, etc. Localities are the Sierra de Cordoba in Argentina, Lake Valley in Sierra county, New Mexico, Arizona, Phoenixville in Pennsylvania, Kappel (Eisen Kappel) near Klagenfurt in Carinthia, and Broken Hill, Rhodesia.

DESCLOT, BERNAT († 2nd half of 13th century), Catalan historian, is known through his chronicle of the life of Peter III of Aragon. It was printed in Barcelona 1616, at Paris in 1840 in *Chroniques étrangères relatives aux expéditions françaises pendant le XIII^e siècle*, and edited by J. Coroleu at Barcelona in 1885.

DESCRIPTION, in the strict sense, means an account of the perceptible qualities or characteristics of objects or events. In this sense it is commonly contrasted with explanation (*g v*), which usually seeks to account for what is perceptible by means of factors and processes which are not open to observation. Extreme empiricists maintain that science should confine itself to bare description and keep clear of any attempt at explanation. It is very easy, however, to smuggle what is really explanation into a so-called description. In the popular use of the term it is clear that a complete description of any object or event would include its explanation.

See A. Wolf, *Foundations of Scientific Method* (1938).

DESCRIPTIVE GEOMETRY is concerned with the method of making accurate drawings to represent completely any object and to solve, with instrumental precision, problems relative to the position and shape of the object. It forms the theoretical basis of all architectural and mechanical drafting, and its practical applications are found in the drawing of machinery, buildings, bridges, vessels, in the representation of shadows and optical projections. It is the means by which the designer conveys his ideas to the builder or mechanic, and has been called the universal language of the engineer.

By the methods of descriptive geometry the solution of any problem concerning three-dimensional objects involves the following steps: (1) representation of the lines, surfaces, or solids in

space by corresponding plane figures, (2) solution of the problem by means of the plane figures, (3) interpretation of this solution as a relation between the objects in space. In order to carry out these steps it is necessary to have a definite scheme by which it is possible to pass without ambiguity from the object in space to its representation by drawings in a plane, and also without ambiguity from the drawings to the object in space again. The scheme now universally used for this purpose was devised about the end of the 18th century by G. Monge (1746-1818).

FIG 1

The **orthographic projection** of a point *a* upon a plane is the point where a line from *a* perpendicular to the plane meets the plane. The orthographic projection of a point *a* in a room upon the floor is the point on the floor directly under the given point *a*. The projection upon a plane of any object in space is the figure on the plane made by projecting each point of the given object. For example (fig. 1) the plane of the square *abcd* is parallel to the

FIG 2

plane *H* and the projection of *abcd* upon *H* is an equal square *a'b'c'd'*. If (fig. 2) the edge *ab* is parallel to *H* but the plane *abcd* is not parallel to *H*, the projection of the square *abcd* on *H* is the rectangle *a'b'c'd'* in which *a'b' = ab* but *b'c'* is less than *bc*. If (fig. 3) the edge *ab* is parallel to *H* and the plane of *abcd* is perpendicular to *H*, the projection of the square *abcd* upon *H* is the straight line *a'b' = ab*. In fig. 4 the plane *abcd* is perpendicular to *H* and the diagonal *ac* is parallel to *H*. In this case the projection of the square is the line *a'c' = ac*.

The line *aa'* which projects a point *a* upon a plane is called a **projecting ray**, or **projector**. In orthographic projection the projecting rays are perpendicular to the plane of projection, consequently all projecting rays are parallel. An oblique projection is obtained when all projecting rays are parallel but are not perpendicular to the plane of projection. Oblique projection is used in the construction of shades and shadows. When the projecting rays are parallel the size of the projection does not depend upon the distance of the object from the plane of projection.

FIG 3

A **scenographic projection**, or **perspective** (see PERSPECTIVE) is obtained when all of the projecting rays converge to a single point, the **point of sight** (fig. 5). This method produces a picture or representation of an object, or group of objects, as it appears to the eye. The size of the scenographic projection of an object depends upon the distances from it to the point of sight and to the plane of projection.

FIG 4

Unless otherwise specified, projection usually means orthographic projection.

Monge's method of representation of an object consists in making orthographic projections of the object on two (or more) planes and establishing a definite relation between the different projections. The two principal planes are the **vertical** (denoted by *V*) and the **horizontal** (denoted by *H*). The line of intersection of these planes is called the **ground line** (denoted by *GL*). Except for special cases *H* and *V* are sufficient for the solution of the problems of descriptive geometry. When a third plane, the **profile plane** (denoted by *P*), is desirable it is taken perpendicular to *GL* and is therefore perpendicular to both *H* and *V*.

The projection of an object on the vertical plane is called the **V projection** or **elevation**, the projection on the horizontal plane is the **H projection** or **plan**. In commercial terminology the elevation is called also the **front view**, or **rear view**, or **sectional elevation**, as the case may be. The plan is called also the **top view**, **bot-**

tom view, or sectional plan Similarly, we have the *profile or end view*

Notation—A systematic notation is necessary for work in descriptive geometry but, unfortunately, no one system has been adopted by a majority of writers on the subject. In this article a point in space is denoted by a small letter, as a , b , the V-projection of a point a is denoted by a^v and the H projection by a^h . A straight line is denoted by two points on it, the two end points if the line is of limited length, as ab (The ground line is denoted by capital letters, GL .) A plane is denoted by a single capital letter, or may be designated by three points in it or by two lines in it.

FIG 5

Representation of a Point—The position of a point a in space is determined if we know its V projection and its H-projection. In fig 6 imagine that H represents the floor of a room and V a wall. The V projection of the point a is a^v , this determines the distance xa^v or height of the point above the floor. The H projection, a^h , determines the length xa^h , or distance of the point from the wall. The position of the point from right to left is not given absolutely by this method, but its position with respect to other points of the object is determined.

The two principal planes of projection are supposed to be unlimited in extent and divide space into four compartments called *quadrants or angles*.

FIG 6

In order to distinguish among these quadrants imagine an observer looking at the planes as they appear in fig 6. He is above H and in front of V. This is the first quadrant. The second is above H and behind V. The third is below H and behind V. The fourth is below H and in front of V. An end view is shown in fig 7.

The method of Monge for representing the position of a point in space by a plane drawing consists in turning the V plane about GL as an axis until it coincides with the H plane. The direction of rotation (fig 7) is such that the upper part of V is made to coincide with the part of H which is behind GL .

It is one of the fundamental relations of orthographic projection that, in space, the two projections of any point together with the point itself must always be in a plane which is perpendicular to GL . After revolving V, the two projections of any point will lie in a straight line which is perpendicular to GL . The relation between a point in space and its plane representation is shown for each quadrant by figs 8-11.

FIG 7

In architectural drawing the objects are usually supposed to be located in the first quadrant, so that the elevation appears above the plan. In engineering drawings the objects are usually in the third quadrant. In perspective drawing the objects are usually in the second quadrant. The fourth quadrant is little used in practice.

Representation of a Line—The orthographic projection of a straight line upon a plane is a straight line, and a straight line in space is represented on the drawing plane by its V-projection and its H-projection. The truth of the three following statements can be made apparent by holding a pencil in various positions with respect to the floor and a wall. In each statement the letters H and V may be interchanged.

1 If a line of definite length is parallel to V alone, its V projection is parallel and equal to the line, and its H projection is parallel to GL .

2 If a line is perpendicular to V, its V-projection is a point, and its H-projection is perpendicular to GL .

3 If a line is parallel to H and V, both of its projections will be parallel to GL .

The projection of a line ab in space will be the lines joining the projections of a and b , that is (fig 12), the V projection of ab is a^vb^v and the H projection is a^hb^h .

In general, any two lines assumed as projections in the plane drawing will determine a line in space. There are, however, excep-

FIG 8

tions when one or both of the projections are perpendicular to the ground line.

A line of indefinite length, which is parallel to neither principal plane, will pierce H in a point called its *horizontal trace* and will

FIG 9

pierce V in its *vertical trace*. These special points are sometimes used to represent the line in the drawing.

Representation of a Plane—A plane of unlimited extent cannot be represented by its projections because, in general, the pro-

FIG 10

jections of all of its points would completely cover both of the principal planes. Hence a plane is represented by its *traces*, that is, the lines in which it cuts the principal planes. The truth of the three following statements can be made apparent by holding a piece of cardboard in various positions with respect to the floor

and a wall. In each statement the letters H and V may be interchanged.

- 1 If a plane is parallel to V, it has no V trace and its H trace is parallel to GL.
- 2 If a plane is perpendicular to V, but oblique to H, its H trace is perpendicular to GL.
- 3 If a plane is parallel to neither principal plane, its traces will

FIG 11

either (a) both be parallel to GL, or (b) intersect GL in the same point.

A profile plane is perpendicular to both H and V. If a plane contains GL, it is represented by its trace on a profile plane.

In the plane drawing (fig. 13) any two lines which meet GL at the same point may be taken as the traces of a plane, and they completely determine the position of the plane in space.

The solution of a problem by the methods of descriptive geometry may be illustrated by the following simple example.

Problem.—To find the true length of a line joining two given points in space.

Solution.—The end points a, b of the line are given, and hence their projections are known.

Theory.—Fig. 14 represents the line ab in space and shows the projection $a'b'$ on the H-plane. Imagine the plane figure $abb'a'$ to be revolved about the line $a'b'$ as an axis into the H-plane. Point a will fall at a' and b will fall at b' . Moreover $a'a$ is perpendicular to $a'b'$ and is equal to $a'a$, $b'b$ is perpendicular to $a'b'$ and is equal to $b'b$.

Construction.—Fig. 15 is the plane drawing representing the given points a, b by their projections. From a' lay off $a'a'$ perpendicular to $a'b'$ and equal to $a'a$. From b' lay off $b'b'$ perpendicular to $a'b'$ and equal to $b'b$. Then $a'b'$ is the true length of ab .

The scope of the operations involving points, lines, and planes in descriptive geometry is indicated by the following partial list of standard problems.

- 1 To find the plane which contains two given intersecting or parallel lines.
- 2 To find the plane which contains a given line and is parallel to a second given line.
- 3 To find the plane which contains a given point and is parallel to each of two given lines.
- 4 To find the plane which contains a given point and is parallel to a given plane.
- 5 To find the plane which contains a given point and is perpendicular to a given line.
- 6 To find the plane which contains a given line and is perpendicular to a given plane.

- 7 To find the line of intersection of two planes.
- 8 To find the point in which a straight line intersects a plane.
- 9 To find the shortest distance from a point to a plane.
- 10 To find the perpendicular distance between two parallel planes.

- 11 To find the projections of a line making given angles with H and V.
- 12 To find the angles which an oblique plane makes with H and V.
- 13 To find the angle between two intersecting lines.
- 14 To find the angle between two planes.
- 15 To find the angle between a line and a plane.
- 16 To find the shortest distance from a point to a line.
- 17 To find the shortest distance between two lines not in the same plane.
- 18 At a given point in a plane, to draw a line which shall be perpendicular to the plane and of given length.

Surfaces.—The methods of descriptive geometry are applicable to the study of curved surfaces in space and of the curves of intersection of such surfaces. The process consists in examining various sections and projections of the figures involved. Of particular interest are those surfaces which can be formed by bending a plane surface without stretching, crumpling, or tearing. Such a surface is called a *developable* surface. Examples are a cylindrical surface (stove pipe) and a conical surface (funnel). A spherical surface is not developable.

An important problem in descriptive geometry is to find the development of a given surface. This means to find the shape of the plane figure which would be obtained by rolling out a given developable surface. The result is illustrated by figs. 16, 17, 18. Fig. 16 represents a truncated right circular cylinder, which means that the lower base is a circle, the elements of the curved surface are perpendicular to the lower base, and the upper base is not parallel to the lower base. Fig. 17 is the development of the curved surface.

Fig. 18 represents the development of the spout of a teapot. The problem involves the intersection of two conical surfaces. The development furnishes a pattern for cutting the metal from which the spout is made.

Shades and shadows are studied by the methods of descriptive geometry. The technical meaning of the terms is shown by fig. 19. The rays of light are supposed to come from a source at a great distance, like the sun, and are regarded as parallel. In conventional drawings the rays are supposed to pass over the left shoulder of the observer at such an angle that their H and V projections make angles of 45° with GL. The illuminated part of an object is that part upon which rays of light fall. *Shade* is that part of an object not exposed to the rays of light. *Line of shade* is the line between the illuminated and shaded parts of an object. The part of unlighted space behind an object in light

FIG 15

FIG 16

FIG 17

FIG 18

FIG 19

is called the *umbra* or *indefinite shadow*. Shadow is the part of a surface in light from which rays of light are excluded by an opaque object. Problems of shades and shadows involve finding the shaded parts of given objects in given positions and the shadows cast by given objects upon other objects.

Descriptive geometry is a regular study in the curriculum of engineering students, and books on the subject are to be found in the list of every prominent publisher of educational texts for technical schools.

(W R L.)
DESCRIPTIVE POETRY, the name given to a class of literature which may be defined as belonging to the 16th, 17th and 18th centuries in Europe. From the earliest times, all poetry which was not subjectively lyrical was apt to indulge in ornament which might be named descriptive. But the critics of the 17th century formed a distinction between the representations of the ancients and those of the moderns. We find Boileau emphasizing the statement that, while Virgil paints, Tasso describes. This may be a useful indication in defining not what should be, but what in practice has been, called "descriptive poetry." It is poetry in which the landscape, or architecture, or still life, or whatever may be the object of the poet's attention, is not used as an accessory, but is itself the centre of interest. It is, in this sense, not correct to call poetry in which description is only the occasional ornament of a poem, and not its central subject, descriptive poetry. The landscape or still life must fill the canvas, or, if human interest is introduced, that must be treated as an accessory. Thomson's *Seasons*, in which landscape takes the central place, and Dryden's *Polioibion*, where everything is sacrificed to a topographical progress through Britain, are strictly descriptive.

It will be obvious from this definition that the danger ahead of all purely descriptive poetry is that it will lack intensity, that it will be frigid, if not dead. Boileau was naturally the first to see this and in verses of brilliant humour he mocked the writer who, too full of his subject, and describing for description's sake, will never quit his theme until he has exhausted it.

Fuyez de ces auteurs l'abondance stérile
Et ne vous chargez point d'un détail inutile

But Boileau's humorous sallies do not quite meet the question whether such purely descriptive poetry as he criticizes is legitimate at all.

In England had appeared the famous translation (1592-1611), by Joshua Sylvester, of the *Drum Weeks and Works* of Du Bartas, containing such lines as those which the juvenile Dryden admired so much:

But when winter's keener breath began
To crystallize the Baltic ocean,
To glaze the lakes, and bridle up the floods,
And perriwig with wool the bald pate woods

There was also the curious physiological epic of Phineas Fletcher, *The Purple Island* (1633). But on the whole it was not until French influences had made themselves felt on English poetry, that description, as Boileau conceived it, was cultivated as a distinct art. The *Cooper's Hill* (1642) of Sir John Denham may be contrasted with the less ambitious *Penshurst* of Ben Jonson, and the one represents the new no less completely than the other does the old generation. If, however, we examine *Cooper's Hill* carefully, we perceive that its aim is after all rather philosophical than topographical. The Thames is described indeed, but not very minutely, and the poet is mainly absorbed in moral reflections. Marvell's long poem on the beauties of Nunappleton comes nearer to the

lengthy poem, generally written in heroic or blank verse. This species of writing had been cultivated to a considerable degree through the preceding century, in Italy and (as the remarks

of Boileau testify) in France, but it was in England that it reached its highest importance. The classic of descriptive poetry, in fact, the specimen which must be considered as the most important and the most successful, is *The Seasons* (1730-30) of James Thomson (q.v.). In Thomson, for the first time, a poet of considerable eminence appeared, to whom external nature was all sufficient, and who succeeded in conducting a long poem to its close by a single appeal to landscape, and to the emotions which it directly evokes. Coleridge, somewhat severely, described *The Seasons* as the work of a good rather than of a great poet, and it is an indisputable fact that, at its very best, descriptive poetry fails to awaken the highest powers of the imagination. A great part of Thomson's poem is nothing more or less than a skilfully varied catalogue of natural phenomena. Yet Thomson succeeds, as few other poets of his class have succeeded, in producing nobly-massed effects and comprehensive beauties such as were utterly unknown to his predecessors. He was widely imitated in England, especially by Armstrong, by Akenside, by Shenstone (in *The Schoolmistress*, 1742), by the anonymous author of *Albany*, 1751, and by Goldsmith (in *The Deserted Village*, 1770). No better example of the more pedestrian class of descriptive poetry could be found than the last-mentioned poem, with its minute and Dutch-like panting:

How often have I paused on every charm
The sheltered cot, the cultivated farm
The never-failing brook, the busy mill,
The decent church that topped the neighbouring hill
The bawthorn-bush, with seats beneath the shade
For talking age and whispering lovers made.

On the Continent of Europe the example of Thomson was almost immediately fruitful. Four several translations of *The Seasons* into French contended for the suffrages of the public, and J. F. de Saint Lambert (1716-1803) imitated Thomson in *Les Saisons* (1769), a poem which enjoyed popularity for half a century, and of which Voltaire said that it was the only one of its generation which would reach posterity. Nevertheless, as Madame du Deffand told Walpole, Saint-Lambert is *frond, fade et faux*, and the same may be said of J. A. Roucher (1745-94), who wrote *Les Mois* in 1779, a descriptive poem, famous in its day. The Abbé Jacques Delille (1738-1813), perhaps the most ambitious descriptive poet who has ever lived, was treated as a Virgil by his contemporaries; he published *Les Géorgiques* in 1769, *Les Jardins* in 1782, and *L'Homme des champs* in 1803, but he went furthest in his brilliant, though artificial, *Trois règnes de la nature* (1809), which French critics have called the masterpiece of this whole school of descriptive poetry. Delille, however, like Thomson before him, was unable to avoid monotony and want of coherency. Picture follows picture, and no progress is made. The satire of Marie Joseph Chénier, in his famous and witty *Discours sur les poèmes descriptifs*, brought the vogue of this species of poetry to an end.

In England, again, Wordsworth, who treated the genius of Thomson with unmerited severity, revived descriptive poetry in a form which owed more than Wordsworth realized to the model of *The Seasons*. In *The Excursion* and *The Prelude*, as well as in many of his minor pieces, Wordsworth's philosophical and moral intentions cannot prevent us from perceiving the large part which pure description takes, and the same may be said of much of the early blank verse of S. T. Coleridge. Since their day, however, purely descriptive poetry has gone more and more completely out of fashion, and its place has been taken by the richer and directer effects of such prose as that of Ruskin in English, or of Fromentin and Pierre Loti in French.

DESERT, a term used for those lands which produce insufficient vegetation to support a human population. Deserts are classified according to the causes which give rise to them. In "cold deserts" the absence of vegetation is consequent on the prevailing low temperature, while in "hot deserts" the causes are high temperatures and deficient rainfall. Cold deserts accordingly occur in high latitudes or high altitudes. Hot deserts are primarily found along the hot, dry tropical belts of high atmospheric pressure, and on their equatorial sides, but the zonal arrangement is considerably modified in some regions by the influence of ele-

vated land. The northern hemisphere provides examples of this type in the African Sahara, the Asiatic deserts of Arabia and Iran, and in the Great Basin of North America. The southern hemisphere has the Kalahari in Africa, the deserts of Western Australia, and the Atacama in South America. Where a line of elevated land runs east and west in this zone as in Asia, the desert belt tends to occur eastwards in higher latitudes but where the line runs north and south, as in Africa, America and Australia, the desert zone weakens on the windward side of the elevation and the arid conditions are accentuated on the lee side. Desert conditions occasionally arise from somewhat obscure local causes, but the Indian desert (*qv*) seems to be situated in a region inaccessible to either of the two main branches of the wet south-west monsoon.

Although permanent rivers rising in wetter regions may traverse deserts (e.g., the Nile) the fundamental physical condition of an area is that it contributes nothing directly to oceanic waters. The rainfall chiefly occurs during violent cloud-bursts (*qv*) and the soluble matter in the soil is carried down by intermittent streams to salt lakes around which deposits of economic value are found on evaporation. Surface erosion is caused by rapid and extreme changes of temperature, while wind action often forms dunes resembling waves. Dry valleys with precipitous sides, and cirque-like heads are probably caused by occasional cloud bursts. Natural springs in some deserts give rise to oases which make trans desert routes possible. When a desert-river has low banks (e.g., the Nile) irrigation is made possible.

See *Das Gestein der Wüstenbildung* by Walther, Berlin, 1900 for a general account of deserts.

DESERTION, the act of forsaking or abandoning, more particularly, the wilful abandonment of an employment, office or duty, in breach of a legal or moral obligation. For naval or military desertion, see **MILITARY LAW**, for desertion from the merchant service, see **LAWS RELATING TO SEAMEN**, for desertion of husband, see **DIVORCE**, for the desertion of children, see **CHILDREN—PROTECTIVE LAWS AND INFANT**.

DESERT WILLOW (*Cholopsis lemniscata*), a small North American tree of the Bignonia family (Bignoniaceae), native to stream banks and the vicinity of springs in deserts from western Texas to southern California and southward to northern Mexico. It grows usually from 8 ft to 25 ft high, with stems from 2 in to 10 in in diameter, slender, ascending branches, and narrow, willow-like leaves. During summer it bears a succession of showy, funnel-shaped, pink flowers, about 1½ in long and 1¼ in across, in profuse terminal clusters, followed in autumn by narrow seed-pods about 8 in long. It is a characteristic plant of southwestern deserts, in appearance suggestive of a slender willow with catalpa-like flowers.

DESFORGES, PIERRE JEAN BAPTISTE CHOU-DARD (1746–1806), French dramatist and man of letters, natural son of Dr Antoine Petit, was born in Paris on Sept. 15, 1746, and educated at the Collège Mazarin and the Collège de Beauvais. After appearing on the stage of the Comédie Italienne in Paris he joined a troupe of wandering actors whom he served in the capacity of playwright. He married an actress, and the two spent three years in St. Petersburg, where they were well received. In 1782 he produced at the Comédie Italienne an adaptation of Fielding's novel with the title *Tom Jones à Londres*. His first great success was achieved with *L'Épave villageoise* (1785) to the music of Grétry. *La Femme jalouse*, a five act comedy, in verse (1785), *Jocote* (1790) for the music of Louis Jadin, *Les Époux divorcés* (1799), a comedy, and other pieces followed. He has left a record of his own early indiscretions in *Le Poète ou mémoires d'un homme de lettres écrits par lui-même* (4 vols., 1798). He died in Paris on Aug. 13, 1806.

DESGARCIAS, MADELEINE MARIE (Louise) (1769–1797), French actress, was born at Mont Dauphin (Hautes Alpes). In her short career she became one of the greatest of French tragédiennes, the associate of Talma, with whom she nearly always played. She made her début at the Comédie Française on May 24, 1788, in *Bayazet*, and was at once made

sociétaire. She left the Comédie Française in 1791 for the house in the Rue Richelieu, soon to become the Théâtre de la République, and there her triumphs were no less—in *King Lear*, *Othello*, *La Harpe's Mélanie et Virginie*, etc. She died insane, in Paris, on Oct. 27, 1797.

DESHAYES, GÉRARD PAUL (1795–1875), French geologist and conchologist, born at Nancy on May 13, 1795, was professor of natural history in the Muséum d'Histoire Naturelle. Deshayes examined the fossil Mollusca of the Paris Basin and of other Tertiary areas. His studies on the relations of the fossil to the recent species led him as early as 1829 to conclusions somewhat similar to those arrived at by Lyell, whom Deshayes assisted in the classification of the Tertiary system into Eocene, Miocene and Pliocene. His chief work, *Mollusques de l'Algérie*, the result of collections made in Algeria, where he was sent by the French Government in 1839, was issued (incomplete) in 1848. He died at Boran, Oise, on June 9, 1875.

DESHOULIÈRES, ANTOINETTE DU LIGIER DE LA GARDE (1638–1694), French poetess, was born in Paris on Jan. 1, 1638. At the age of 13 she married Guillaume de Boisguernin, seigneur Deshoulières, who followed the prince of Condé to the wars. Madame Deshoulières returned for a time to the house of her parents, where she wrote poetry and studied the philosophy of Gassendi. She rejoined her husband at Rocroi, near Brussels, and was imprisoned in the château of Wilwörden because of her insistence that her husband's arrears of pay should be met. After a few months she was freed by her husband, who attacked the château at the head of a small band of soldiers. They were amnestied, and returned to France, where Madame Deshoulières soon became a conspicuous personage at the court of Louis XIV and in literary society, some of her more zealous flatterers even going so far as to style her the tenth muse and the French Calliope. Voltaire pronounced her the best of French poetesses, and she was elected a member of the Academy of the Ricovrati of Padua and of the Academy of Arles. In 1688 she was pensioned by the king. She died in Paris on Feb. 17, 1694. Complete editions of her works were published at Paris in 1695, 1747 and 1882 (edit. Lescure). These include a few poems by her daughter, Antoinette Thérèse Deshoulières (1656–1718), who inherited her talent.

See Sainte-Beuve, *Portraits de femmes* (1892).

DESICCATION, the operation of drying or removing water from a substance. It is of particular importance in practical chemistry. If a substance admits of being heated to say 100°, the drying may be effected by means of a steam bath, which is simply an oven heated by steam, an air bath may be used for higher temperatures. Otherwise a desiccator must be employed, this is essentially a closed vessel in which a hygroscopic substance is placed together with the substance to be dried. The process may be accelerated by exhausting the desiccator, this so-called vacuum desiccation is especially suitable for the concentration of aqueous solutions of readily decomposable substances. Hygroscopic substances in common use are phosphoric anhydride, concentrated sulphuric acid, potassium and sodium hydroxides, soda lime, anhydrous sodium sulphate and calcium chloride.

Two common types of desiccator are in use. In one the absorbent is placed at the bottom, and the substance to be dried above, in the other, this arrangement is inverted. Liquids are dried either by means of the desiccator, or, as is more usual, by shaking with a substance which removes the water. Fused calcium chloride is the commonest absorbent, but it must not be used with alcohols and certain other liquids with which it forms compounds. Quicklime, barium oxide and dehydrated copper sulphate are especially applicable to alcohol and ether, the last traces of water may be removed by adding metallic sodium and distilling. Gases are dried by leading them through tower or tube, containing an appropriate drying material. The experiments of H. B. Baker on the influence of moisture on chemical combination have shown the difficulty of removing the last traces of water.—Dr. F. S. DUFFY, CHICAGO.

In chemical technology, apparatus on the principle of the

laboratory air bath is mainly used. Crystals and precipitates, deprived of as much water as possible by centrifugal machines or filter-presses, are transported by means of a belt, screw or other form of conveyor, on to trays staged in brick chambers heated directly by flue gases or steam pipes, the latter are easily controlled, and if the steam be superheated a temperature of 300° and over may be maintained. In some cases the material traverses the chamber from the coolest to the hottest part on a conveyor or in wagons. Rotating cylinders are also used, the material to be dried is placed inside, and the cylinder heated by a steam jacket or otherwise.

DESIDERIO DA SETTIGNANO (1428-1464), Italian sculptor, was born at Settignano, near Florence, and was for a short time a pupil of Donatello, whom, according to Vasari, he assisted in the work on the pedestal of David, and he seems to have worked also with Mino da Fiesole, with the delicate and refined style of whose works those of Desiderio seem to have a closer affinity than with the perhaps more masculine tone of Donatello. It does not appear that Desiderio ever worked elsewhere than at Florence, for there are to be found there his few surviving decorative and monumental works, though a number of his delicately carved marble busts of women and children are to be found in the museums and private collections of Germany and France. The most prominent of his works are the tomb of the secretary of state, Marsuppini, in Santa Croce, and the great marble tabernacle of the Annunciation in San Lorenzo, both of which belong to his later period, and the cherubs' heads which form the exterior frieze of the Pazzi chapel. Vasari mentions a marble bust, by Desiderio, of Marietta degli Strozzi, which has been identified as a marble portrait bust acquired by the Berlin museum in 1842. The Berlin museum also owns a coloured plaster bust of an Urbino lady, by Desiderio. Other important busts by the master are in the Bargello, Florence, the Louvre in Paris and in private collections.

See Wilhelm Bode, *Die stahenische Plastik* (Berlin, 1893).

DESIDERIUS, the last king of the Lombards, is chiefly known through his connection with Charlemagne. He was duke of Tuscany and became king of the Lombards in 756. Seeking to extend the Lombard power, he came into collision with the papacy, and about 772 Adrian I, implored the aid of Charlemagne against him. Other causes of quarrel already existed between the Frankish and the Lombard kings. In 770 Charlemagne had married a daughter of Desiderius, but he soon sent her back to her father. Moreover, Gerberga, Charlemagne's sister in law, had sought the protection of the Lombard king after her husband's death in 771. Desiderius had recognised her sons as the lawful Frankish kings, and had attacked Adrian for refusing to crown them. Such was the position when Charlemagne took the Lombard capital, Ticinum, the modern Pavia, in June 774, and appropriated the kingdom of Lombardy. Desiderius was carried to France, where he died, and his son, Adalgis, spent his life in futile attempts to recover his father's kingdom.

See S. Abel, *Untergang des Langobardenreichs* (Göttingen, 1859), and *Jahrbücher des fränkischen Reiches unter Karl dem Grossen* (Leipzig, 1865), Paulus Diaconus, *Historia Langobardorum*, ed by L. Bethmann and G. Woltz (Hanover, 1878), L. M. Hartmann, *Geschichte Italiens im Mittelalter* (Gotha, 1903).

DESIGN is the arrangement of lines or forms which make up the plan of a work of art with especial regard to the proportions, structure, movement and beauty of line of the whole. A design may be naturalistic or wholly the abstract conception of the artist. Its structure is related to the structure of the frame and the rendering of the subject, but not to the structure or anatomy of the subject itself. A design may be successful which is incorrect in every detail of anatomy. Design in one sense is synonymous with composition, and has to do with all the arts, though more pronounced in the applied arts than in the fine arts.

The Japanese artist Korin arrived at much of his design through the selection of certain parts of purely natural arrangements which were simplified and selected as typical, but which were rendered in a naturalistic manner. Much of modern design is not so made up, but consists of gross distortion for the over-

stressing of structure or movement, with a complete loss of other characteristics. This type of design is so close to caricature that it often detracts rather than adds to the beauty of a work of art.

Design is concerned not only with typical movement but also with typical rhythms. Through the medium of parallel master strokes or accenting of repeating movements, rhythms are set

FIG 1—PROGRESSIVE STEPS IN THE FORMING OF A SWASTIKA WITHIN A SQUARE.

up which should, like the rhythms of great poetry, accent the meaning and express a crystallization of the personality of the artist, and at the same time of his subject as seen through his eyes. Just as in "The Raven" by Poe, we have the summing up of all of Poe's mood in his work and at the same time have the summing up of the expression of all human despair in the bird's recurring "Never more," so in the design of a master of the graphic arts will be found accents and rhythms which build the mood he wishes to establish. Design is to the graphic arts what verse form and rhyme are to poetry: the ladder up which it climbs to the heights. Design can exist without colour, but just as there can be design in line and mass so there can also be design in colour, based upon the distribution of harmoniously blending or contrasting tones, when design is present in both line and colour the two must work together to further the effect of the conception. Every element of art can be designed separately and in relation to the other elements. Thus there can be structural design, movement design, outline design. (See DRAWING.)

Teaching—In the teaching of design it is often helpful to have the student cut out various pieces of paper representing

FIG 2—DEVELOPMENT OF WAVE OR VINE DESIGN WITHIN PARALLEL LINES FROM SIMPLE GEOMETRICAL FORM.

the main areas to be used and move them about within the size area, cut out of the centre of another piece of paper, upon which he is to work. When these have been arranged to his satisfaction, lines should be thrown in which tie the whole together, and finally, with these established areas and lines to guide him, work can be begun. The Chinese artist does this mentally as he sits contemplating the silk upon which he is to paint, for he has trained his mind to remember the arrangement once he has de-

ided upon it. The student can teach himself to do this, but it is well to begin with the more objective method.

It is interesting to note that in given areas only a certain number of effective designs are possible, and that man has hit upon them in every part of the world without intercommunication. Scientists have tried to prove a common origin for the race because of the almost universal use of the swastika, but many

FIG. 3—PROBABLE EVOLUTION OF TYPICAL PERSIAN OGGEE DESIGN FROM OLD ZOROASTRIAN MOTIF

children have never seen this sign arrive at it spontaneously, when left to decorate squares. The steps are simple (see fig. 1).

(1) The corners, which catch the eye quickest for a starting point, are joined, (2) the sides, (3) both are combined and before long, in the age old attempt to represent movement, the spurs are discovered and all sorts of variations follow. The "wave" or "vine" or "running" border is developed in like manner, because it is the most obvious way to decorate a narrow space between parallel lines. We usually find (A) the geometrical treatment (fig. 2), (B) the curve with open areas which are soon (C) filled with spots assuming the shape of leaves on a vine as time goes on (D), and an excuse for their being is demanded. Finally, as in (E), the movement is increased and it becomes on many Tzu Chow vases of China a leaping rather than a running border, representative of waves from which the fiery dragon ascends.

Development.—The typical Persian ogee design has an interesting origin which is demonstrable on existing vases. In fig. 3 (A) is shown the old Zoroastrian motif of the rising sun which only loosely filled the border, other suns were introduced at a still earlier period. In a further attempt to build the border together a design was inserted between them, which sometimes held written characters and finally, as the religion is developed, the suns disappear and ogee patterns are fitted together, becoming a typical national motif.

Design is, therefore, old and has been thought of for many thousand years, and the student does well to acquaint himself with early examples found in various parts of the world. It is almost as difficult to create a new design as it is to discover a new geometric principle, but another element enters design, and once having learned it as one would learn geometry, there is available, instead of a cold, mathematical deduction, a vehicle for the expression of one's personal sense of beauty. (W. E. C.)

ORIGINALITY

Modern use has tended to associate design with the word "original" in the sense of new or abnormal. But the end of design is utility, fitness and delight. If a discovery, it should be a discovery of what seems inevitable—an inspiration arising out of the conditions, and parallel to invention in the sciences. The faculty of design has best flourished when an almost spontaneous development was taking place in the arts, and while certain classes of arts, more or less noble, were generally demanded and the demand copiously satisfied, as in the production of Chinese porcelain, Greek vases, Byzantine mosaics, Gothic cathedrals and Renaissance paintings. Thus where a "school of design" exists there is much general likeness in the products but also a general progress. The common experience—"tradition"—is a part of each artist's stock in trade, and all are carried along in a stream of continuous exploration. Some of the arts, writing for instance, have been little touched by conscious originality in design all has been progress, or, at least, change, in response to conditions. Under

such a system, in a time of progress, the proper limitations react as intensity, when limitations are removed the designer has less and less upon which to react, and unconditional liberty gives him nothing at all to lean on. Design is response to needs, conditions and aspirations. The Greeks so well understood this that they appear to have consciously restrained themselves to the development of selected types, not only in architecture and literature, but in domestic arts, like pottery. Design with them was less the new than the true.

For the production of a school of design it is necessary that there should be a considerable body of artists working together, and a large demand from a sympathetic public. A process of continuous development is thus brought into being which sustains the individual effort. It is necessary for the designer to know familiarly the processes, the materials and the skilful use of the tools involved in the productions of a given art, and properly only one who practises a craft can design for it. It is necessary to enter into the traditions of the art, that is, to know past achievements. It is necessary, further, to be in relation with nature, the great reservoir of ideas, for it is from it that fresh thought will flow into all forms of art. These conditions being granted, the best and most useful meaning we can give to the word design is exploration, experiment, consideration of possibilities. Putting too high a value on originality other than this is to restrict natural growth from vital roots, in which true originality consists. To take design in architecture as an example, we have rested too much on definite precedent (a different thing from living tradition) and, on the other hand, hoped too much from newness. Exploration of the possibilities in arches, vaults, domes and the like, as a chemist or a mathematician explores, is little accepted as a method in architecture at this time, although in antiquity it was by such means that the great master works were produced: the Pantheon, Santa Sophia, Durham and Amiens cathedrals. The same is true of all forms of design. Of course the genius and inspiration of the individual artist is not here ignored, but assumed. What we are concerned with is a mode of thought which shall make it most fruitful. (See ARTS AND CRAFTS, RENDERING, ARCHITECTURAL. (W. R. L.))

DESK, any kind of flat or sloping table for writing or reading. Its earliest shape was probably that with which we are familiar in pictures of the monastic *scriptorium*—rather high and narrow with a sloping slab. The primitive desk had little accommodation for writing materials, and no storage room for papers, drawers, cupboards and pigeonholes were the evolution of periods when writing grew common, and when letters and other documents requiring preservation became numerous. It was long the custom to secure papers in chests or cabinets, whereas the modern desk serves the double purpose of a writing-table and a storehouse for documents. The first development from the early slab desk consisted of the addition of a drawer, then the table came to be supported upon legs or columns. Eventually the legs were replaced by a series of superimposed drawers forming pedestals—hence the familiar pedestal writing-table.

For a long period there were two distinct contemporary forms of desk—the table and the bureau or escarot. The latter shape attained a popularity so great that it was found even in houses in which there was little occasion for writing. The English-speaking people of the 18th century were amazingly fond of pieces of furniture which served a double or triple purpose. The bureau—the word is the French generic appellation for a desk—derives its name from the material with which it was originally covered (*fr. bureau*, woollen cloth). It consists of an upright cabinet sloping in at the top and provided with long drawers below. The upper part is fitted with small drawers and pigeon holes, and often with secret places, and the writing space is formed by a hinged slab supported on runners, when not in use this slab closes up the sloping top. During the 18th century innumerable thousands of these bureaux were made on both sides of the Atlantic—in fact, in we accept tables and chairs, no piece of old furniture is more common. In the first part of that period they were usually of oak, but when mahogany was introduced into Europe it speedily ousted the heavier looking wood. Its deep rich colour and the

high polish of which it was capable added appreciably to its ornamental appearance. While the pigeon-holes and small drawers were used for papers, the long drawers were often employed for purposes other than literary. In time the bureau-secretaire became a bureau bookcase, the glazed shelves, which were often a separate erection, resting upon the top of the bureau. The cabinet makers of the second half of the 18th century, the period of the greatest

floraison of this combination, competed with each other in devising elegant frets for the glass fronts. Solid and satisfying to the eye, if somewhat severe in form, the mahogany bureau was usually an exceedingly presentable piece of furniture. Occasionally it had a bombé front which mitigated its severity, this was especially the case in the Dutch varieties, which were in a measure free adaptations of the French Louis Quinze commode. These Dutch bureaux, and the English ones made in imitation of them, were usually elaborately inlaid with floral designs in coloured woods, but whereas the Batavian marquetry was often rough and crude, the English work was usually of considerable excellence. Side by side with this form of writing apparatus was one variety or another of the writing-table proper. In so far as it is possible to generalize upon such a detail it would appear that the bureau was the desk of the yeoman and what we now call the lower middle class, and that the slighter and more table like forms were preferred by those higher in the social scale.

Just about the time when the flat table with its drawers in a single row was finally assuming its familiar modern shape, an invention was introduced which was destined eventually to supersede all other forms of desk. This was the cylinder top writing-table. Nothing is known of the originator of this device, but it is certain that if not French himself he worked in France. The historians of French furniture agree in fixing its introduction about the year 1750, and we know that a desk worked on this principle was in the possession of the French crown in the year 1760. Even in its early days the cylinder took more than one form. It some-

A SCRIBE OF THE XVIIth CENTURY WORKING AT HIS DESK

and to the facility with which the closing of the cylinder can cease all papers, and automatically locks every drawer. To France we owe the construction of many of the finest and most historic desks that have survived—the characteristic marquetry writing tables of the Boule period, and the gilded splendours of that of Louis XV have never been surpassed in the history of furniture. Indeed, the "Bureau du roi" which was made for Louis XV is the most famous and magnificent piece of furniture that, so far as we know, was ever constructed. This desk, which is now one of the treasures of the Louvre, was the work of several artist artificers, chief among whom were Oeben and Riesener—Oeben, it may be added here as a matter of artistic interest, became the grandfather of Eugene Delacroix. The bureau is signed *Riesener fa 1769 à l'Arsenal de Paris*, but it has been established that, however great may have been the share of its construction which fell to him, the conception was that of Oeben. The work was ordered in 1760, it would thus appear that nine years were consumed in perfecting it, which is not surprising when we learn from the detailed account of its construction that the work began with making a perfect miniature model followed by one of full size. The "bureau du roi" is a large cylinder desk elaborately inlaid in marquetry of woods, and decorated with a wonderful and ornate series of mounts consisting of mouldings, plaques, vases and statuettes of gilt bronze cast and chased. These bronzes are the work of Duplessis, Winant and Hervieux. The desk, which shows plainly the transition between the Louis XV and Louis XVI styles, is as remarkable for the boldness of its conception as for the magnificent finish of its details. Its lines are large, flowing and harmonious, and although it is no longer exactly as it left the hands of its makers, (Oeben died before it was finished) the alterations that have been made have hardly interfered with the general effect. For the head of the king for whom it was made, that of Minerva in a helmet was substituted under his successor. The ciphers of Louis XV have been removed and replaced by Sèvres plaques, and even the key which bore the king's initial crowned with laurels and palm leaves, with his portrait on the one side, and the fleur de lys on the other, has been interfered with by an austere republicanism. Yet no tampering with details can spoil the monumental nobility of this great conception. (J P-B)

DESMARETS or DESMARETZ, JEAN, SIEUR DE SAINT-SORLIN (1595-1676), French dramatist and miscellaneous writer, was born in Paris in 1595. The success of his romance *Ariane* in 1617 led to his admission to the circle that met at the house of Valentin Conrart and later developed into the Académie Française. Desmarets was its first chancellor. He began to write for the theatre at the request of his patron Richelieu. In this kind he produced a comedy long regarded as a masterpiece, *Les Visionnaires* (1637), a prose-tragedy, *Erigone* (1638), and *Scapion* (1639), a tragedy in verse. His success brought many official preferences. His long epic *Cléon* (1657) is noteworthy because Desmarets rejected the traditional pagan background and maintained that Christian imagery should supplant it. With this standpoint he contributed several works in defence of the moderns in the quarrel between the Ancients and the Moderns. In his later years Desmarets wrote religious poems. He was a violent opponent of the Jansenists, against whom he wrote a *Réponse à l'écclésiastique apologetique de Port Royal* (1666). He died in Paris on Oct. 28, 1676.

See also H. Rigault, *Histoire de la querelle des anciens et des modernes* (1836), pp. 80-103 and R. Kerviler, *Desmarets* (1899).

DESMARETS, NICOLAS, SIEUR DE MAILLEBOIS (1648-1711), French statesman, was born in Paris, Sept. 10, 1648. He was a nephew of J. B. Colbert, rose rapidly in the financial administration, and was disgraced after Colbert's death. In 1686 he was recalled, and during the next ten years presented to the controllers general a series of remarkable memoirs exposing the desperate economic situation of France. He held office under Chamillart from 1699 onwards, and in 1708 succeeded him as controller general. The situation was exceedingly grave. The ordinary revenues of the year 1708 amounted to 81,977,007 livres, of which 57,833,233 livres had already been anticipated, and the expenses to meet were 200,251,447 livres. In 1709 a famine reduced still more the tax

BY COURTESY OF THE METROPOLITAN MUSEUM OF ART
AN XVIIIth CENTURY CYLINDER DESK IN LOUIS XVIth STYLE

times consisted of a solid piece of curved wood and sometimes of tambour frame—that is to say, of a series of narrow jointed strips or wood mounted on canvas, the revolving shutter of a shop front, an adaptation of the idea. For a long period, however, the cylinder was most often solid, and remained so until the latter part of the 19th century when the "American roll top desk" began to be made in large numbers. This is indeed the old French form with a tambour cylinder, and it is now the desk that is most frequently met with all over the world for commercial purposes. Its popularity is due to its large accommodation

returns Emission of paper money, and an improved collection of taxes tided over the years of 1709 and 1710 Then Desmarests decided upon an income tax His "tenth" was based on Vauban's plan, but the privileged classes managed to avoid it After the death of Louis XIV Desmarests was dismissed by the regent and withdrew to his estates He was certainly, after Colbert, the greatest finance minister of Louis XIV's reign See Forbonnais, *Recherches et considérations sur les finances de la France* (2 vols Basel, 1758), Montyon, *Particularités et observations sur les ministres des finances de la France* (1812), De Bousille, *Correspondance de contrôleurs-généraux des finances* (3 vols 1873-97), and the same author's "Desmarests et l'affaire des pièces de quatre sols" in the appendix to the seventh volume of his edition of the *Mémoires de Saint Simon*

DES MOINES, the capital and largest city of Iowa, U.S., in the south central part of the state, on the Des Moines river, at the mouth of the Racoon, a port of entry and the county seat of Polk county It is on federal highways 6, 65 and 69, has municipal and commercial airports and is served by the Burlington, the Chicago and North Western, the Chicago Great Western, the Chicago, Milwaukee, St. Paul and Pacific, the Fort Dodge, Des Moines and Southern, the Minneapolis and St. Louis, the Rock Island and the Wabash railways, by air lines and interurban motorbus and trolley lines and additional railways for freight only

The population in 1950 was 176,954, and in 1940 was 159,819, of which 89.4% were native white and 6.5% foreign-born white

The city lies on both banks of the river, at an altitude of 861 ft, and has an area of 55.91 sq mi The state capitol (completed in 1882 at a cost of \$3,000,000) stands on an eminence in a park of 80 ac Near by is the State Historical, Memorial and Art building and the state library Des Moines was one of the first among U.S. cities to plan on a relatively generous scale for beauty in its development A comprehensive city plan was adopted in 1924 and considerable progress was made in carrying it out Along the river front, through the heart of the city, extends the civic centre, with a city hall (\$500,000), a municipal courthouse (\$600,000), a federal building and a post office The city's system of parks and playgrounds covers 1,400 ac, and the grounds of the state fair, which has an attendance of around 500,000 each year, have an area of 600 ac The Des Moines Art centre in Greenwood park, designed by Eliel Saarinen, was opened in 1948 It comprises a museum, library, auditorium and school

Drake university, a privately endowed educational institution founded in 1881, is located in northwest Des Moines and covers 34 ac in the metropolitan area of the city The university has eight colleges and a graduate division It operates the Drake-Des Moines observatory, located in Waveland park The Drake-Des Moines symphony orchestra is another co-operative undertaking of the city and the school The Drake relay, founded in 1910, attracts thousands of spectators and athletes each April

Adjoining the city on the south is Ft. Des Moines, formerly an important army post where almost a full regiment of cavalry was stationed besides various other troops During World War II it was the first training centre for the women's army corps It was later converted into a veterans' housing centre At Camp Dodge, 11 mi N., now used by the national guard thousands of soldiers were trained during World Wars I and II

In 1907 the city adopted a commission form of government known as the "Des Moines plan," which was superseded in 1950 by a city-manager plan

In the heart of the corn belt, and surrounded by a coal field which has produced as much as 3,000,000 tons in a year, Des Moines is an important commercial centre The jobbing business of more than 500 wholesale houses amounted to more than \$559,766,000 annually at mid-20th century

Incoming and outgoing freight totals 2,500,000 tons in a year, and 200 package-freight cars leave the city daily Manufactures also are important, with an output in 1949 valued at \$340,000,000 Chief among them are meat products, flour, clothing, foundry products, brick and tile, aircraft parts and farm machinery The printing and publishing of newspapers and periodicals is one of

the leading industries The city is the principal centre for the publication of farm journals It is the home of *Better Homes and Gardens*, and *Look* magazines

A number of insurance companies, with aggregate assets of \$1,165,000,000 at mid century, have their home offices there

In 1843 a military post called Ft. Des Moines was established on the site of the city to protect the rights of the Sacs and Foxes, and in the same year the district was opened to settlement by the whites The town was incorporated in 1851 In 1857 it was chartered as a city and was made the State capital, superseding Iowa City The population in 1860 was 3,965, which grew to 12,035 in 1870, 22,408 in 1880, and 50,093 in 1890 Between 1890 and 1920, without any annexations of territory, the population increased 152% The fort was re established in 1900 The name of city and fort was taken from that of the river, which is supposed to be a corruption of the original Indian name, *Momonga*, by the French, who at first, using the abbreviation *mom*, called it *la rivière des moms*, and later, through its association with the Trappist monks, changed it to *la rivière des monnes*

DESMOND, EARLS OF *see* FITZGERALD, DESMOND, GERALD FITZGERALD, 15TH EARL OF

DESMOND, GERALD FITZGERALD, 15TH EARL OF (d. 1833), Irish leader, was son of James, 14th earl, by his second wife More O'Carroll Young Gerald was to have been educated in England as the companion of the young king, Edward VI Unfortunately for the subsequent peace of Munster these projects were not carried out Claims on the Desmond estates were made by the Butlers, the hereditary enemies of the Geraldines, but temporary peace was made by Gerald's marriage with the daughter and heiress of the 11th earl of Desmond, who had previously married, first, the 9th earl of Ormonde and secondly, Sir Francis Bryan

Gerald succeeded to the earldom in 1558, he was knighted by the lord deputy Sussex, and did homage at Waterford He allied himself with his namesake Gerald Fitzgerald, 11th earl of Kildare (1525-1585), and with Shane O'Neill, and trouble was renewed between Ormonde and the Fitzgeralds Desmond, summoned to appear in London to account for the misdeeds of his clan, delayed his appearance until May 1562 He was detained in London for two years, and after his return the death of his wife freed him from such restraint as had existed Open war followed, and Desmond was defeated and taken prisoner Desmond and his brother Sir John of Desmond were sent over to England, where they surrendered their lands to the queen after a short experience of the Tower

Desmond was allowed to return to Ireland in 1573 He was detained for six months in Dublin, but in November slipped through the hands of the Government, and in a short time had reduced the province to a state of anarchy On July 18, 1574, the Geraldine chiefs signed the "Combination" promising to support the earl unconditionally, shortly afterwards Ormonde and the lord deputy, Sir William Fitzwilliam, marched on Munster, and put Desmond's garrison at Derrinlaur Castle to the sword Desmond submitted at Cork on Sept. 2, handing over his estates to trustees Sir Henry Sidney visited Munster in 1575, and affairs seemed to promise an early restoration of order But Fitzmaurice had fled to Brittany in company with other leading Geraldines He intrigued at the French and Spanish courts for a foreign invasion of Ireland, and at Rome met the adventurer Stucley, with whom he projected an expedition which was to make a nephew of Gregory XIII king of Ireland In 1579 he landed in Smerwick bay, where he was joined later by some Spanish soldiers at the Fort del Ore His ships were captured on July 29, and he himself was slain in a skirmish while on his way to Tipperary Desmond had perhaps been restrained before by jealousy of Fitzmaurice, his indiscretions ceased when on Nov. 1 Sir William Pelham proclaimed him a traitor The sack of Youghal and Kinsale by the Geraldines was speedily followed by the successes of Ormonde and Pelham acting in concert with Admiral Waterbury In June 1581 Desmond had to take to the woods, on Nov. 11 he was seized and murdered by a small party of soldiers His brother Sir John of Desmond had been caught and killed in Dec. 1581, and John Fitz-

Juan expedition (1779), then made governor of the Mosquito shore and the Bay of Honduras, and in 1782 commander of a successful expedition against the Spanish possessions on the Black river. In 1784 he took over the administration of Yucatan. Upon frivolous charges he was suspended by Lord Grenville, and recalled to England. From 1790 to 1792 these charges were held over him, and when dismissed no compensation was forthcoming. His complaints caused his arrest in 1798, and with a short interval he remained in gaol until 1800. Despard was arrested on a charge of plotting to assassinate George III, tried before a special commission, found guilty of high treason, and, with six of his fellow-conspirators, sentenced in 1803 to be hanged, drawn and quartered. These were the last men to be so sentenced in England. Despard was executed on Feb. 21, 1803.

His eldest brother, JOHN DESPARD (1745-1829), had a long and distinguished career in the British army, gazetted an ensign in 1760, he became general in 1814. In the American War of Independence he was twice made prisoner.

See Sir Charles Oman, *The Unfortunate Colonel Despard and other studies* (1922).

DESPATCH or DISPATCH, to send off immediately, or by express, particularly in the case of the sending of official messages, or of the immediate sending of troops to their destination, or the like. The word is used as a substantive of written official reports of events, battles and the like, sent by ambassadors, generals, etc., by means of a special messenger, or of express correspondence generally. From the primary meaning of the prompt sending of a message, the word is used of the quick disposal of business, or of the disposal of a person by violence. The French word *dépêche* came into England as *depeach*, which was in use from the 15th century until "despatch" was introduced. An early use of "despatch" occurs in a letter to Henry VIII from Bishop Tunstall, commissioner to Spain in 1516-17.

DESPENSER, HUGH LE (d. 1265), chief justiciar of England, first played an important part in 1258, being prominent on the baronial side in the Mad Parliament of Oxford. In 1260 the barons chose him to succeed Hugh Bigod as justiciar, and in 1263 the king was further compelled to put the Tower of London in his hands. On the outbreak of civil war he joined the party of Simon de Montfort, earl of Leicester, and led the Londoners when they sacked the manor-house of Isleworth, belonging to Richard, earl of Cornwall, king of the Romans. Having fought at Lewes (1264) he was made governor of six castles after the battle, and was then appointed one of the four arbitrators to mediate between Simon de Montfort and Gilbert de Clare, earl of Gloucester. He was summoned to Simon de Montfort's parliament in 1265, and acted as justiciar throughout the earl's dictatorship. Despensers were killed at Evesham in Aug. 1265.

See C. Bémont, *Simon de Montfort* (Paris, 1884); T. F. Tout in *Oxford Historical Essays*, pp. 76 ff. (Manchester, 1902).

DESPENSER, HUGH LE (1262-1326), English courtier, was a son of the justiciar, fought for Edward I in Wales, France and Scotland, and in 1295 was summoned to parliament as a baron. Ten years later he was sent by the king to Pope Clement V. to secure Edward's release from the oaths he had taken to observe the charters in 1297. Almost alone Hugh spoke out for Edward II's favourite, Piers Gaveston in 1308, but after Gaveston's death in 1312 he himself was the king's chief adviser until Edward's defeat at Bannockburn in 1314. Then, hated by the barons, and especially by Earl Thomas of Lancaster, as a deserter from their party, he was driven from the council, but was quickly restored to favour and loaded with lands and honours, being made earl of Winchester in 1322. Before this time Hugh's son, the younger Hugh le Despenser, had become associated with his father, and was enjoying a still larger share of royal favour. About 1306 this baron had married Eleanor (d. 1337), one of the sisters and heresses of Gilbert de Clare, earl of Gloucester, who was slain at Bannockburn, and after a division of the immense Clare lands had been made in 1317 violent quarrels broke out between the Despensers and the husbands of the other heiresses, Roger of Amery and Hugh of Audley. Interwoven with this dispute was another between the younger Despenser and the Mowbrays, who

were supported by Humphrey Bohun, earl of Hereford, about some lands in Glamorganshire. Fighting having begun in Wales and on the Welsh borders, the English barons showed themselves decidedly hostile to the Despensers, and in 1321 Edward II was obliged to consent to their banishment. The elder Hugh left England for a time, but father and son were soon again at court. They fought against the rebellious barons at Boroughbridge, and after Lancaster's death in 1322 they practically ruled the country. But their next enemy, Queen Isabella, was more formidable, or more fortunate, than Lancaster. Returning from France in 1326 the queen directed her arms against her husband's favourites. The elder Despenser was seized at Bristol, where he was hanged on Oct. 27, 1326, and the younger was taken with the king at Llantrissant and hanged at Hereford on Nov. 24. The attainer against the Despensers was reversed in 1398. The intense hatred with which the barons regarded the Despensers was due to the enormous wealth which had passed into their hands, and to the arrogance and rapacity of the younger Hugh. The younger Despenser left two sons, Hugh (1308-49), and Edward, who was killed at Vannes in 1342.

The latter's son EDWARD LE DESPENSER (d. 1375) fought at the battle of Poitiers, he was a patron of Froissart, who called him *le grand sire Despensier*. His son, THOMAS LE DESPENSER (1373-1400), the husband of Constance (d. 1416), daughter of Edmund of Langley, duke of York, supported Richard II against Thomas of Woodstock, duke of Gloucester, and the other lords appellant in 1397, when he himself was created earl of Gloucester, but he deserted the king in 1399. Then, degraded from his earldom for participating in Gloucester's death, Despensers joined the conspiracy against Henry IV, but he was seized and executed by a mob at Bristol in January 1400.

The elder Edward le Despenser left another son, HENRY (c. 1341-1406), who became bishop of Norwich in 1370. In early life Henry had been a soldier, and when the peasants revolted in 1381 he took readily to the field, defeated the insurgents at North Walsham, and suppressed the rising in Norfolk with some severity. Pope Urban VI in 1382 employed him to lead a crusade in Flanders against the supporters of the anti-pope Clement VII. After capturing several towns he was checked at Ypres, and defeated by the French. On his return the bishop was impeached and deprived of his lands, Richard II, however, stood by him. Almost alone among his peers Henry remained true to Richard in 1399, he was then imprisoned, but was quickly released. He died on Aug. 23, 1406. Despensers was an active enemy of the Lollards, whose leader, John Wycliffe, had fiercely denounced his crusade in Flanders.

The barony of Despenser, called out of abeyance in 1604, was held by the Fanes, earls of Westmorland, from 1626 to 1762, by the notorious Sir Francis Dashwood from 1763 to 1781, and by the Stapletons from 1788 to 1891. In 1891 it was inherited, through his mother, by the 7th Viscount Falmouth.

DES PÉRIERS, BONAVENTURE (c. 1500-1544), French author, was born of a noble family at Arnay-le-duc in Burgundy at the end of the 15th century. In 1533 or 1534 Des Périers visited Lyons, then the most enlightened town of France, and a refuge for many liberal scholars. He gave some assistance to Robert Olivetan and Lefèvre d'Étaples in the preparation of the vernacular version of the Old Testament, and to Étienne Dolet in the *Commentarii linguae latinae*. In 1536 he put himself under the protection of Marguerite d'Angoulême, queen of Navarre, who made him her *valet de chambre*. He acted as the queen's secretary, and transcribed the *Heptaméron* for her. It is probable that his duties extended beyond those of a mere copyist, and some writers have gone so far as to say that the *Heptaméron* was his work. The free discussions permitted at Marguerite's court encouraged a licence of thought as displeasing to the Calvinists as to the Catholics. This free enquiry became scepticism in Bonaventure's *Cymbalum Mundi* (1537), and the queen of Navarre disavowed the author, though she continued to help him privately until 1541. The book consisted of four dialogues in imitation of Lucian. Its allegorical form did not conceal its real meaning, and the Sorbonne secured the suppression of the edi-

tion (c 1538) before it was offered for sale. The book was reprinted in Paris in the same year. It made many bitter enemies for the author. Henri Estienne called it *détestable*, and Etienne Pasquier said it deserved to be thrown into the fire with its author if he were still living. Des Périers prudently left Paris, and settled at Lyons, where in 1544 he put an end to his existence by falling on his sword. In 1544 his collected works were printed at Lyons. The volume, *Recueil des oeuvres de Jean Bonaventure des Périers*, included his poems, which are of small merit, the *Traité des quatre vertus cardinales après Sénèque*, and a translation of the *Lysis* of Plato. In 1558 appeared at Lyons the collection of stories and fables entitled the *Nouvelles récréations et joyeux devis*, the work on which his fame rests. Some of the tales are attributed to the editors, Nicholas Demot and Jacques Pelletier, but their share is certainly limited to the later ones. The stories are models of simple, direct narration in the vigorous and picturesque French of the 16th century.

His *Oeuvres françaises* were published by Louis Lacour, 2 vol. (Paris, 1856). See also the preface to the *Cymbalum Mundi*, ed by F. Franck (1874); A. Chenevère, *Bonaventure Des Périers, sa vie, ses poésies* (1885); and P. Toldo, *Contributo allo studio della novella francese del XV e XVI secolo* (Rome, 1895).

DES PLAINES, a city of Cook county, Ill., U.S., on the Des Plaines river about 17 mi N.W. of Chicago. It is on federal highways 12, 14 and 45 and is served by the Chicago and North Western and Soo railways. The population was 14,975 in 1950 and 9,518 in 1940 by the federal census. Founded in the 1830s and originally called Rand after the first settler, Socrates Rand, it adopted its modern name in 1869 after the river flowing through the community. The municipal government is of the mayor council type, the waterworks are municipally owned and operated. There is some industry, including electrical appliance and tool manufacturing, and extensive greenhouses, although many of the employed are commuters to Chicago.

In 1860 the city became the site of a Methodist encampment which, occupying a wooded area along the river, has many summer homes, a large auditorium and a swimming pool.

DESPORTES, PHILIPPE (1546-1606), French poet, was born at Chartres in 1546. As secretary to the bishop of Le Puy he visited Italy, where he gained a knowledge of Italian poetry. He then attached himself to the duke of Anjou, and followed him to Warsaw on his election as king of Poland. Nine months in Poland satisfied the civilized Desportes, but in 1574 his patron became king of France as Henry III and gave the poet the abbey of Tiron and four other valuable benefices. A good example of the light and dainty verse in which Desportes excelled is furnished by the well-known *villanelle* with the refrain "Qui premier s'en repentira," which was on the lips of Henry, duke of Guise, just before his tragic death. Desportes imitated Petrarch, Lodovico Ariosto, Jacopo Sannazaro and still more closely the minor Italian poets, and in 1604 a number of his plagiarisms were exposed in the *Reconcontres des Muses de France et d'Italie*. As a sonneteer he showed much grace and sweetness, and English poets borrowed freely from him. In his old age Desportes prepared a translation of the Psalms remembered chiefly for the brutal motif of *Malherbe*. *Votre potage vaut mieux que vos psalmes*. Desportes died on Oct. 5, 1606, leaving the reputation of the courtier poet.

BIBLIOGRAPHY—Desportes had published in 1573 an edition of his works including *Diane*, *Les Amours d'Épiphonie*, *Élégies*, *Bergeries*, *Oeuvres chrétiennes*, etc. A splendid edition printed by Étienne appeared in 1579. An edition of his *Oeuvres*, by Alfred Michiels, was published in 1858.

DESPOT, in Greek usage the master of a household, hence the ruler of slaves (Gr *despotēs*, lord or master). It was also used by the Greeks of their gods, but was principally applied to the absolute monarchs of the eastern empires, and it is in this sense that the word, like its equivalent "tyrant," is in current usage for an absolute sovereign whose rule is not restricted by any constitution. In the Roman empire of the east "despot" was used as a title of honour or address of the emperor, and later of his sons, brothers and sons-in-law. Later still it was adopted by the vassal princes of the empire. This gave rise to the name "despotats" applied to the tributary states which survived the

breakup of the empire in Epirus, Cyprus, Trebizond, etc.

Under Ottoman rule the title was preserved by the despots of Serbia, etc.

DES PRES, JOSQUIN (c 1445-1521), also called **DEPRES** or **DESPREZ**, and by a latinized form of his name, **JODOCUS PRATENSIS** or **A. PRATO**, French musical composer, was born, probably in Condé in the Hennegau, about 1445. He was a pupil of Joannes Ockeghem, and himself one of the most learned musicians of his time. In spite of his great fame, the accounts of his life are vague and the dates contradictory. In his early youth Josquin seems to have been a member of the choir of the collegiate church at St. Quentin, when his voice changed he took lessons in counterpoint from Ockeghem, afterward he again lived at his birthplace for several years and probably spent some time at various Italian courts until he joined the papal chapel in Rome in 1486. In Rome Des Prés lived till 1494, and it was there that many of his works were written. He was considered by his contemporaries to be the greatest master of his age. Martin Luther, who was a good judge, is credited with the saying that "other musicians do with notes what they can, Josquin what he likes." The composer's journey to Rome marks in a manner the transference of music's headquarters from the north to Italy, which for the next two centuries remained the centre of the musical world. To Des Prés and his pupils Jacob Arcadelt, Jean Mouton and others, much that is characteristic in modern music owes its rise, particularly in their influence upon Italian developments under Palestrina. After leaving Rome Josquin accepted an invitation of King Louis XII of France to become the chief singer of the royal chapel. He was also, for a time at least, in the service of the emperor Maximilian I, and at the time of his death, on Aug. 27, 1521, was a canon of the cathedral of Condé.

The most complete list of his compositions—consisting of masses, motets, psalms and other pieces of sacred music—will be found in F. Pétis. The largest collection of his ms. works, containing no fewer than 20 masses, is in the possession of the papal chapel in Rome. During the 17th and 18th centuries Josquin's value was ignored, nor does his work appear in the collections of G. Martini and G. Paolucci. C. Burney was the first to recover him from oblivion, and J. Forkel continued the task of rehabilitation. A. Ambros furnishes an exhaustive account of his achievements. An account of Josquin's art will be found in the article "Josquin," by the Rev. J. R. Milne in Grove's *Dictionary of Music and Musicians*, 3rd ed., vol. 1. An edition of the complete works of Josquin was undertaken by the *Vereeniging voor Noord-Nederlandsche Musiekgeschiedenis* under the editorship of A. Smijers. Seventeen of Josquin's masses were published during his lifetime by Perrucci (1502-16), and two others in 1539 by Johannes Ott at Nuernberg. Many of his motets were printed in various collections, notably in Commers's *Collectio operum musicorum Batavorum* (12 vol., 1840), and another selection of his works was edited by R. Elmer.

DESPRES, SUZANNE (1875-), French actress, was born at Verdun, and trained at the Paris Conservatoire. She then became associated with, and subsequently married, Aurelien Lugné-Foe, the actor-manager, who had founded a new school of modern drama, L'Oeuvre, and she had a brilliant success in several plays produced by him. In succeeding years she played at the Gymnase and at the Porte Saint Martin, and in 1902 made her debut at the Comédie Française, appearing in *Phèdre* and other important parts.

DESRUES, ANTOINE FRANÇOIS (1744-1777), French poisoner, was born at Chartres in 1744, of humble parents. He went to Paris to seek his fortune, and started in business as a grocer. He was known as a man of great piety and devotion, and his business was reputed to be a flourishing one, but when, in 1773, he gave up his shop, his finances, because of personal extravagance, were in a deplorable condition. Nevertheless he entered into negotiations with a Madame de la Mothe for the purchase from her of a country estate, and when the time came for the payment of the purchase money, invited her to stay with him in Paris pending the transfer. While she was still his guest, he poisoned

first her and then her son, a youth of 16. Then, having forged a receipt for the purchase money, he endeavored to obtain possession of the property. But by this time the disappearance of Madame de la Mothe and her son had aroused suspicion. Desrues was arrested, the bodies of his victims were discovered, and the crime was brought home to him. He was tried, found guilty and condemned to be torn asunder alive and burned. The sentence was carried out (1777). Desrues repeating hypocritical protestations of his innocence to the last. The whole affair created a great sensation at the time, and as late as 1828 a dramatic version of it was performed in Paris.

DESSAIX, JOSEPH MARIE, COUNT (1764-1834), French general, was born at Thonon, Haute Savoie, on Sept. 24, 1764. He studied medicine, took his degree at Turin and then went to Paris, where in 1789 he joined the national guard. In 1791 he tried without success to raise an *émeute* in Savoy. In 1792 he organized the "legion of the Allobroges," and served at the siege of Toulon, in the army of the eastern Pyrenees and in the army of Italy. Dessaix was elected a member of the council of five hundred, and opposed the coup d'état of the 18th Brumaire (Nov. 9, 1799). Promoted general of brigade in 1803, he fought at Wagram (1809), was made general of division and in 1810 a count. He took part in the expedition to Russia, and was for some time commandant of Berlin. He joined Napoleon in the hundred days, and in 1816 was imprisoned for five months. He died on Oct. 26, 1834.

See *Le Général Dessaix, sa vie politique et militaire*, by his nephew Joseph Dessaux (Paris, 1879).

DESSAU, the capital city of the Land of Anhalt, Germany, on the left bank of the Mulde, 2 mi. from its confluence with the Elbe, 67 mi. S.W. from Berlin and at the junction of lines to Cöthen and Zerbst. Pop. (1939), 120,744.

Dessau, probably founded by Albert the Bear, had attained civic rights as early as 1213. It grew into importance at the close of the 17th century, after the religious emancipation of the Jews in 1686, and of the Lutherans in 1697.

Apart from the old quarter on the Mulde, the town is well built with spacious squares such as the Grosse Markt and the public buildings of a capital. The Schlosskirche is adorned with paintings by Lucas Cranach, in one of which ("The Last Supper") are portraits of several reformers. The former ducal palace, standing in extensive grounds, contains a collection of historical curiosities and a gallery of pictures, which includes works by Cimabue, Fra Filippo Lippi, Peter Paul Rubens, Titian and Sir Anthony Van Dyck, the Amalienstift also has a picture gallery. Dessau manufactures sugar, chocolate, chemicals, small iron goods and machinery, various household objects and some textiles. There is also a considerable trade in corn and garden produce. Because of its airfield, its importance as a railway centre and as the seat of the great Junkers plane factory, Dessau was frequently bombed by the British in World War II.

DESSEWFY, AUREL, COUNT (1808-1842), Hungarian journalist and politician, eldest son of Count József Dessewffy and Eleonora Szatmari, was born at Nagy-Mihály, County Zemplén, Hung. Carefully educated at his father's house, he was accustomed to the best society of his day. While still a child he could declaim most of the *Iliad* in Greek without a book, and read and quoted Tacitus with enthusiasm. He regularly accompanied his father to the diets of which he was a member, followed the course of the debates, of which he kept a journal, and made the acquaintance of Count Stephen Széchenyi, who encouraged his aspirations. On leaving college, he entered the royal aulic chancellery, and in 1832 was appointed secretary of the royal stadtholder at Buda. The same year he turned his attentions to politics and was regarded as one of the most promising young orators of the day, especially during the sessions of the diet of 1832-36, when he had the courage to oppose Lajos Kossuth. At the Pressburg diet in 1840 Dessewffy was already the leading orator of the more enlightened and progressive Conservatives, but incurred great unpopularity for not going far enough, with the result that he was twice defeated at the polls. But his reputation in court circles was increasing, he was appointed a member

of the committee for the reform of the criminal law in 1840, and the same year, with a letter of recommendation from Metternich in his pocket, visited England and France, Holland and Belgium, made the acquaintance of Louis Thiers and Heinrich Heine in Paris, and returned home with an immense and precious store of practical information. He at once proceeded to put fresh life into the despondent and irresolute Conservative party and the Magyar aristocracy by gallantly combating in the *Világ* the opinions of Kossuth's paper, the *Pesti Hírlap*. But the multiplicity of his labours was too much for his feeble physique, and he died on Feb. 9, 1842.

DESSOIR, LUDWIG (1810-1874), German actor, whose name was originally Leopold Dessauer, was born on Dec. 15, 1810, at Posen, the son of a Jewish tradesman. He made his first appearance on the stage there in 1824 in a small part. After some experience at the theatre in Posen and on tour, he was engaged at Leipzig from 1834-36. In 1836 he was at the Breslau municipal theatre, and during 1837-39 at Budapest. From there he went to Karlsruhe and in 1847 to Berlin where his success in *Othello* and *Hamlet* won him a permanent engagement at the Hof theatre. In 1853 he appeared in London. He retired in 1872 and died on Dec. 30, 1874, in Berlin. Dessoir was twice married, by his first wife he had one son, the actor Ferdinand Dessoir (1836-92). In spite of certain physical disabilities Ludwig Dessoir's genius raised him to the first rank of actors, especially as an interpreter of Shakespeare's characters. G. H. Lewes placed Dessoir's *Othello* above that of Edmund Kean, and the *Athenaeum* preferred him in this part to Brooks or W. Macready.

DE STEFANI, ALBERTO (1879-), Italian economist and statesman, was born at Verona on Oct. 6, 1879. Educated at the University of Padua he became professor of political economy at the Superior Commercial Institute of Venice. In 1921 he was returned to the chamber as a Fascist and was Mussolini's first minister of finance. Later he was also entrusted with the treasury department and welded the two into a single ministry. He abolished useless expenditure and simplified the fiscal system, reducing innumerable taxes to three main sources of revenue, with the result that, in three years a deficit of 6,500,000,000 lire was converted into a surplus of 209,000,000. His measures for restraining speculation in the currency and stock markets during the financial slump in the spring of 1925 were less successful, he lost the confidence of the banking community, and in July was superseded by Count Giuseppe Volpi.

DESTOUCHES, PHILIPPE (1680-1754), French dramatist, whose real name was Nércault, was born at Tours. He was attached successively to the French embassies in Switzerland and in London, and married a Lancashire lady, Dorothea Johnston. On his return to France (1723) he was elected to the Academy. He died July 4, 1754. His early comedies were *Le Curieux im pertinent* (1710), *L'Ingrat* (1712), *L'Irrésolu* (1713) and *Le Médiant* (1715). The best of these is *L'Irrésolu*, in which Dorante, after hesitating throughout the play between Julie and Célimène, marries Julie, but concludes with the reflection — "J'aurais mieux fait, je crois, d'épouser Célimène."

After 11 years of diplomatic service Destouches returned to the stage with the *Philopote marie* (1727), followed in 1732 by his masterpiece *Le Glorieux*, a picture of the struggle then beginning between the old nobility and the wealthy *parvenus* who found their opportunity in the poverty of France. Among his later comedies may be mentioned *Le Tambour nocturne* (1736), *La Force du naturel* (1750) and *Le Dissipateur* (1736).

His works were issued in collected form in 1755, 1757, 1811 and, in a limited edition (6 vol.), 1822. See J. Graziano, *Essai sur la vie et les œuvres de Destouches* (1889), A. Burner, *Destouches et ses comédies* (1906), J. Hankins, *Philippe Nércault Destouches, Poète et Poésiste* (1918).

DESTROYER. The modern destroyer, one of the most versatile of combat vessels, was the product of approximately 50 years of evolution in naval design. During that time, it grew from a small 200-ton ship built to repel torpedo boats to 2,000- or 3,000-ton craft capable of dealing destruction to anything afloat, under the sea or in the air.

It was not until the latter part of the 19th century brought

DESTROYERS OF THE 20TH CENTURY

- 1 USS Waters, flush deck destroyer of World War I Displacement 1,090 tons
- 2 HMS Vanoc, a World War I destroyer of the Admiralty V class Displacement 1,090 tons
- 3 USS Maddox, destroyer of the Allen M. Sumner class representative of the World War II period Displacement 2,200 tons
- 4 HMS Zambesi, World War II destroyer Displacement 1,710 tons
- 5 The German destroyer Hans Ludemann, which was sunk by HMS Warspite, and British destroyers in the second battle of Narvik, 1940 Displacement 1,811 tons
- 6 The Italian destroyer Leone, sunk by British naval aircraft in the Red sea 1941 Displacement 1,526 tons
- 7 USS Robert A. Owens, escort destroyer of the Carpenter class completed after World War II and fitted with electronic equipment and armament for anti-submarine activity Displacement 2,500 tons
- 8 HMS Battaxe, post World War II anti-submarine destroyer

great improvements in the manufacture of high powered explosives that the destroyer had its beginning. With improved explosives, the underwater torpedo became a definite menace to even such large ships as battleships, and to carry the torpedoes to their targets, small, fast torpedo boats were built. It soon became apparent that the best defense against torpedo boats was more small, faster boats, and these craft were classified as torpedo-boat destroyers. Through a process of continued improvement in design, resulting in increased speed, power and armament, the torpedo boat destroyer eventually eliminated the torpedo boat (at least for many years) and took over its duties, becoming known as the destroyer.

First such vessels built for the U.S. navy were a group of sixteen 420-ton boats, authorized during the Spanish American War. All coal burners, they were stricken from the navy list in 1930, by which time the destroyer building program had progressed through eight classes and the navy was then sailing the famous World War I flush deck destroyers, or "four pipers" as they were called by destroyer sailors even during World War II. The World War I building program saw the completion of 111 "Wicks" class and 136 "Clemson" class destroyers, many of which were still in service in modified form at mid-20th century as mine sweepers or high speed transports. Although World War I operations against Germany in the Atlantic gave the destroyers very little actual combat, it was a testimonial to U.S. shipbuilding practice and naval training that these destroyers were still in fighting trim 25 years later, as was particularly evidenced by some of them in brilliant action against superior Japanese forces in the Java Sea campaign early in 1942. Fifty of these two types were transferred to Great Britain in 1940, in which service nine were lost in wartime action, and in 1944 ten of those remaining were again transferred, this time to the USSR.

With the addition to the fleet, commencing in 1934, of the "Farragut" class ships, the destroyer building program received continued attention and acceleration, until the end of World War II in 1945. During that time construction had progressed through 14 additional classes, and approximately 600 destroyers were in service when the war ended.

U.S. destroyers are named for deceased naval, marine and coast guard personnel who rendered distinguished service, secretaries and assistant secretaries of the navy, members of congress and inventors closely connected with naval affairs, while destroyer escorts commemorate personnel of the aforementioned services killed in enemy action in World War II. From such famous naval men as Stephen Decatur, Isaac Hull, James Lawrence and Thomas Truxtun, the roster of destroyer and escort names runs through history to Destroyer 537, the "Sullivans," named for five brothers lost on the cruiser "Juneau" in the Solomon campaign.

Originally planned as a single purpose craft and designed to operate in divisions and squadrons, usually in support of larger fleet units, the destroyer's evolution into a craft of unlimited abilities had commenced well before World War I. Convoy escort and submarine warfare had been added to their duties in World War I, the latter duty depending on underwater listening devices and depth charge attack. Development of carrier aviation made plane guard destroyers a necessary part of carrier operations, where they served as antisubmarine screen and performed rescue work in case of crashes. Protection of the slower-moving battle line was accomplished by destroyer-laid smoke screens and by torpedo attack against opposing light forces.

Because of rapid technical advances in many fields of naval warfare, the modern destroyer was a different and far more dangerous ship than the earlier types. Probably the least changed of its weapons were the depth charges, or "ash cans," the principal antisubmarine threat. Submarine warfare, however, was greatly intensified by the use of radar and sonar, which enabled destroyers to track submarines in any condition of weather or visibility, whether surfaced or submerged, while the radiotelephone communications made it possible for several destroyers to corner a submarine and subject it to highly concentrated depth charge attack. The effectiveness of such tactics was reflected in a compilation

of Japanese war losses, which credited United States destroyers with sinking 47 out of 130 submarines lost as a result of all Allied action.

Destroyer fire power, greatly increased by rapid-firing 5-in. guns effective against either surface or aerial targets and controlled from a central location through "director fire," was made still more deadly by the use of radar and proximity-fused shells. The installation of many automatic firing 20 and 40 mm guns enabled destroyers to put up a fierce anti aircraft fire, which took no small toll of enemy aircraft.

Improved torpedoes, with greater range at higher speed, plus improved fire control systems and more effective detonators, gave destroyers a new "Sunday punch" effective against anything afloat, the best example of this occurred in the battle of Surigao strait during the Philippine occupation, when the Japanese battleship "Fuso" went down under a destroyer torpedo attack.

In the most outstanding World War II innovation of naval warfare, the amphibious landings, destroyers again proved invaluable. Because of their shallow draught and high manoeuvrability, they were able to operate with comparative safety in waters dangerous for heavier vessels, where their high-powered and accurate fire was used in pin point shore bombardment. For the same reasons, destroyers were able to carry out rescue operations impossible for larger ships, notably evacuations of troops at Normandy and Crete by British destroyers, and the rescue of 1,000 survivors of the U.S. cruiser "Helena" from a Japanese-held island in the Pacific.

In postwar conversions of destroyer-type vessels, the U.S. navy developed another destroyer modification, called the destroyer-hunter killer. Twelve such vessels were completed during late 1949 and early 1950. In general appearance, the hunter-killers closely resembled other ships in their class, but were considerably altered to fit them for antisubmarine warfare. In addition to usual destroyer armament, they carried various fittings and devices still in the experimental stage. They were designed for use in hunter killer teams, consisting usually of several destroyers, an aircraft carrier with embarked planes and possibly a heavy patrol plane or lighter-than-air ship, all working together in a highly organized group.

Stripped of its outer covering, a destroyer proves to be a hull almost filled with machinery and little else. Four oil-fired high-pressure steam boilers produce steam at pressures up to 600 lb per square inch. Superheated to 850° F, the steam is fed to turbines developing up to 60,000 h.p., which drive twin screws through reduction gears. Evaporators and condensers transform sea water into fresh water for the boilers. Dynamos provide electrical current to train the guns, hoist ammunition and boats, diesel driven generators provide power if the dynamos fail. A myriad of pumps and thousands of feet of pipe carry oil and water to the boilers, salt water to ballast tanks and various fire-fighting stations, and fresh water throughout the ship for various uses. Powerful electric blowers keep up air pressure in the firerooms and other blowers ventilate the ship. Complicated and intricate electrical and electronic devices steer the ship, aim its fire guns and torpedoes, maintain radar watch for planes and other ships, make sonar search for submarines, and navigate the ship by use of loran and dead reckoning tracers. A telephone system provides communication throughout the ship, while radio phones keep it in communication with other ships and planes.

Although much was added to the destroyer during the course of its development, little was left off, the hull is so packed with machinery that provision for the crew appears to have been made only as an afterthought. While admittedly crowded, destroyer quarters are, in themselves, no less comfortable than those of other ships.

Destroyer types, in various modifications, are included in all navies, but their characteristics vary with the strategical situations which they may be expected to encounter. France and Italy, for instance, with a limited sphere of naval influence, favoured high speed ships, while Great Britain and the United States, with protection of ocean commerce and long sea lanes in mind, tended to sacrifice some speed for greater cruising radius. Destroyer

Comparison of U.S. Destroyer Types with Types Constructed by Other Nations

Type	United States		Great Britain		France	Italy
	Fletcher	Gearing	Battle	Daring	Le Fantasque	Granatiere
Number built	173	105	24	8	4	9
Building years	1942-47	1942-43	1944-46	1945-47	1911-12	1918
Overall length	376 ft 4 in	300 ft	300 ft	300 ft	435 ft	336 ft

	ten 21 in TT	ten 21 in TT	ten 21 in TT	ten 21 in TT	six 21 in TT	six 21 in TT

*Installations of 50- and 40 mm batteries vary.

†For Fletcher class ships originally had one torpedo tube mount removed.

‡Later removed and ships armed to conform to test of class.

§Ten trials. "Le Terrible" of this class averaged 43 knots for eight hours.

¶Not announced.

building in the United States and Great Britain and, for a while, Japan, was limited by terms of the London Naval treaty, while Italy and France, not so limited, tended to build larger ships. Destroyers ranging from 2,500 to 3,500 tons were serving with Italian, French, Japanese, Netherlands and Russian fleets during World War II. Japan lost 134 destroyers during the war, and Italy lost 131. The United States lost 84 of all classes.

DESTRUCTORS This term is applied, particularly in England, by municipal engineers, to a battery of high-temperature furnaces constructed for disposing, by burning, of household and town refuse. Messrs. Manlove, Alliott and Co., of Nottingham, first registered the word destructor as its special trade name for such a furnace. (For developments in the United States, see REFUSE DISPOSAL.) The first destructor built by this firm under Fryer's patent was erected in Manchester in 1874. Disposal of refuse is not, however, the only consideration. Utilization of refuse as fuel for steam production is also important. Many towns systematically utilize the calorific value of refuse.

A proper degree of caution, however, should be exercised when contemplating the use of refuse as a low grade fuel. When its value for this purpose was first recognized it was believed that the refuse of a given population was of itself sufficient to develop the necessary steam-power for supplying that population with their electric lighting requirements. The supposed economic importance of a combined destructor and electric undertaking of this character possibly had much to do, in some districts, with the development both of the adoption of the principle of dealing with refuse by fire and of lighting by electricity. Engineering experience, however, very often has shown this to be impractical. But, under favourable circumstances, determining the merits in each case, useful service to other power-using undertakings, such as sewage pumping, clinker crushing plants, etc., may be obtained.

Composition of Refuse.—The composition of house refuse, which obviously affects its calorific value, varies widely in different districts. The following is an analysis of refuse as dealt with in destructors, based on the average of 12 towns in Great Britain. The percentages of the various constituents are as follows—fine dust 45.45, 4 in to 4 in and large cinders 36.16, bricks, pots, shale, etc., 6.5, tins 1.3, rags 5.4, glass 8.3, bones 0.9, vegetable refuse 4.05, scrap iron 4.2, boots 2.6, fish offal, greens, small paper bags, carpet, oil cloth, boots, etc., 2.4 per cent.

In London, the quantity of house-refuse amounts approximately to from 4 cwt. to 5 cwt. per head per annum, or to from 200 to 250 tons per 1,000 of the population per annum. Statistics, however, vary widely in different districts. At Ipswich 7 cwt. per 1,000 of the population per working day are collected, whereas, at Merthyr Tydfil 40 cwt. per 1,000 people per day are produced. Recent data show the normal quantity collected to lie between 15 and 20 cwt. per 1,000 people per day. When estimating the required capacity of a destructor plant, the quantity of refuse produced

by the particular town in question must first be independently investigated, and all calculations based accordingly.

A cubic yard of ordinary house-refuse weighs from 12 to 15 cwt. but varies according to its condition whether wet or dry, etc. Shop refuse often consists largely of paper, packings, straw and cardboard. Its weight may be as little as 7 cwt. per cubic yard.

Methods of Disposal.—Various methods of disposal of refuse are adopted by different towns according to local facilities and

conditions. Owing to the high costs involved after World War I in the working of refuse destructors, a system of controlled tipping upon suitable land has been largely resorted to, notably at Bradford, where some 45 tips within the city boundaries are in use. The refuse is spread in layers of about 8 ft in depth and regularly covered with soil. By this means waste land, old quarries, etc., are reclaimed for future use as parks and open spaces. Pulverization of refuse has been adopted in some towns. The refuse is crushed to a small gauge, and where possible disposed of as manure, but the difficulty of securing a reliable market is usually considerable. When obtained such markets are not to be relied upon with any certainty of continuity. Another means of disposal is by the separation or salvage system. In this case the dust, cinders, paper, rags, glass, metals, tins, etc., are all separately sorted out and sold where markets can be found. The vegetable and other putrescible constituents are burned. The handling and redistribution of refuse material in this way amongst the population cannot be regarded with favour in the interests of public health. Disposal at sea and sinking in deep water are also practised, but is often rather costly and sometimes unsatisfactory.

The Destructor System.—The destructor system in which the refuse is burned to an innocuous clinker in specially constructed high-temperature furnaces is that which is most generally resorted to when other methods have proved unsatisfactory, especially in districts which have become well built up and thickly populated. Conditions regarding this method of disposal have, however,

neating stoves, the high price of coal and the more economical habits of householders, have all contributed to the production of house refuse with a smaller proportion of cinders and scraps of coal, thereby resulting in a low calorific value, and also a poorer quality of clinker from the destructor furnace. At Farnborough it was found that the calorific value of refuse was about 50% less than in pre-World War I days, and there was similar experience at Southampton, Hull and elsewhere.

Many of the earlier destructor and electricity station combinations have not proved satisfactory for various reasons, and have been abandoned. One difficulty often experienced has been that of maintaining a steady and reliable steam pressure with so variable and uncertain a fuel.

A number of destructor-electric combinations are, however, working satisfactorily in districts where the local conditions are favourable, as at Rhondda, Wolverhampton and Pontypool. At Rhondda and Pontypool the refuse is of a high calorific value, and contains a relatively large percentage of small coal and unburnt cinders. During an official test, the Rhondda destructor (Heenan and Froude) evaporated 4.15 lb of water per 1 lb of refuse burned from and at 212°. This destructor was erected

in 1915, and the South Wales Power Co purchased the electric current produced at this installation. The electrical energy generated is equal to 264 units per ton of refuse burnt.

The electrical output at the Rhondda destructor plant has not been equalled by any combined destructor and electric station. Other power-using services to which the surplus heat from a destructor is applied include the pumping of low level sewage, as carried out at Salisbury, Lincoln, Cambridge, Watford, Eastbourne, Luton, Felkistowe, Aldershot and Twickenham.

During recent years, the question of high running costs at destructor installations has been under careful review by many British public authorities, and many destructors have either been discontinued or rendered of limited service.

Conditions for Destructor System.—As regards the general question of the advisability or otherwise of erecting a destructor, each town should decide for itself, according to the local conditions and requirements. It is a question upon which it is unwise to generalize, but when considering the matter, some leading points to be kept in view are: (a) Is the district so closely built up and congested as to render all other less costly means of disposal impracticable, thus rendering the expense of a destructor necessary as a last resort? (b) Has the refuse sufficient calorific value to justify its use for steam raising purposes, and are there any necessary local services, such as sewage pumping, upon which the heat from the destructor can be profitably utilized, and thus save the cost of coal as a set off against the heavy working expenses? (c) Are any local markets available for the sale of surplus clinker, tins, etc.? (d) Can a suitable central site for a destructor be found in a populated area without involving additional expense in haulage to some outlying site, or causing nuisance from smells, dust, and the concentrated cartage of refuse, to the neighbouring inhabitants? (e) Can the existing system of disposal be carried on without risk of real danger (as distinguished from sentiment) to the public health? If not, the installation of a destructor must then be seriously considered.

Although the conditions arising out of the World War placed a check in Great Britain, in the United States and on the Continent upon the laying down of new destructor installations, and the maintenance of existing plants, the past few years have shown a renewal of activity in this direction.

Notwithstanding high capital costs and working expenses, necessity arising out of local conditions has led to the erection of new plants at Birmingham, Hornsey, Devonport, Rochdale, Wimbledon, Portsmouth, Brighton, Llandudno, East Ham, Hastings, Leicester, Leeds, Hereford, Accrington, Coventry, Edinburgh, Perth, Stoke, New York, Gibraltar and elsewhere.

Modern Equipment.—A modern installation usually includes, in addition to the leading feature of the destructor cells or furnaces, a mechanical power driven plant used in connection with the preliminary screening of the refuse and comprising screens, elevators, etc., for the removal of dust up to about $\frac{1}{16}$ in gauge, an overhead runway for conveyance of hot clinkers from the furnace mouths, and storage accommodation for raw refuse for use when the collectors are not at work.

For the removal of tins and iron from the raw refuse electromagnetic separators are frequently installed where these materials have a marketable value. The tins are reduced in bulk to convenient blocks by means of a hydraulic baling-press. Clinker from the furnaces is reduced to saleable form by suitable clinker-crushing and screening plants. Other accessory machinery includes a strongly built mortar mill and a hydraulic press for the manufacture of slab-paving in order to utilize the surplus clinker, a power driven fan with air-ducts for the supply of forced draught to the cells. Machinery for the manufacture of asphalt from clinker for the surfacing of roadways is in some cases also installed, as, e.g., at Brighton and Abertrillery. The motive-power for actuating all this accessory plant at the destructor station, including an electric lighting equipment, is usually economically obtainable from the surplus heat from the cells when applied to the generation of steam in a suitable boiler.

Forced Draught.—The forced draught to destructor cells may be given by an air fan or by steam blast. The air fan will

require to work at about 6 in total water-gauge pressure, and to give from 2 in to 3 in of pressure in the asphalt itself. The actual pressure will vary according to the thickness of the fires being burnt at any given time. The power required to drive the air fan suitable for six furnaces of the Sterling type (New Destructor Co., Ltd.) will not exceed 25 brake horse power.

In the case of steam blast with 2 in to 2½ in water gauge pressure in the asphalt, the quantity of steam used per hour would be approximately 1,000 lb in four Heenan cells, or 250 lb of steam per hour per grate of 305 sq ft area. The temperature required to be developed in the combustion chamber is approximately 2,000°. The advantages of forced draught are that a much higher temperature is attained, little more air than the quantity theoretically necessary is needed, and the minimum amount of cold air is admitted to the furnaces. The air supply to modern furnaces is usually delivered hot—the inlet air being first passed through an air-heater the temperature of which is maintained by the waste heat in the main flue.

Types of Cells.—The evolution of a good type of destructor cell or furnace, has occupied many years of experience, and has been the subject of much experiment and many failures. The principal towns in England which took the lead in the adoption of the destructor were Manchester, Birmingham, Leeds, Warrington, Blackburn, Bradford, Bury, Hull, Nottingham, Ealing and London. Ordinary furnaces, built mostly by dust contractors, began to come into use in London and in the north of England in the second half of the 19th century, but they were not scientifically adapted to the purpose, and necessitated the admixture of coal with the refuse to ensure its proper cremation.

The Manchester Corporation erected a furnace of this kind about the year 1873-74, and Messrs Mead and Co made an unsatisfactory attempt in 1876 to burn house-refuse in closed furnaces at Paddington. Shortly after Alfred Fryer erected his destructor at Manchester, several other towns also adopted this furnace. Other types were from time to time brought before the public, among which may be mentioned those of Pearce and Lupton, Pickard, Hesley, Whitley, Thwaite, Young, Wilkinson, Burton, Hardie, Jacobs and Ogden. In addition to these the Beehive and the Nelson destructors became well known. The former was introduced by Stafford and Pearson of Burnley, and one was built in 1884 in the parish yard at Richmond, Surrey, but the results being unsatisfactory, it was closed during the following year. The Nelson furnace, patented in 1885 by Messrs Richmond and Birtwistle, was erected at Nelson in-Marsden, Lancashire, but, being costly in working, was abandoned.

Types of Destructors.—The principal types of destructors now in use are those of Fryer, Warner, Manlove-Alliott, Meldrum, Beaman and Deas, Heenan and Froude, and the Horsfall and Sterling destructor. The Fryer destructor was patented by Alfred Fryer in 1876. The cells are usually arranged in pairs back to back, and enclosed in a rectangular block of brickwork having a flat top on which the house refuse is tipped from the carts. The furnace burns from four to six tons of refuse per cell per 24 hours. The outlets for the products of combustion are placed at the back near the refuse feed openings. This arrangement is imperfect in design as it permits offensive vapours from unburnt refuse to escape into the main flue with the products of combustion. Nuisances from smell arising from this cause led, in some instances, to the introduction of a secondary furnace, known as a cremator, which was patented by C. Jones of Ealing in 1885. This furnace was placed in the main flue leading to the chimney shaft for the purpose of cremating the organic matters in the vapours from the unburnt refuse, but it added considerably to the cost of running the destructor and was abandoned. The Fryer destructor, with a cremator, was largely used during the early history of destructors, but it has given place to more modern and improved designs of high temperature furnaces.

The Horsfall destructor is a high-temperature furnace of later design than the foregoing. Important improvements are to be found in the arrangement of the flues and flue outlets for the products of combustion, and in the provision of a forced draught duct through which air is supplied under pressure into a closed

FIG 1—CROSS SECTION THROUGH HEENAN DESTRUCTOR SYSTEM

Showing dust screening plant and entire course of the refuse from arrival in the refuse-collecting vehicle to its destruction in the furnaces

asphalt. The flue opening for the removal of gaseous products of combustion is placed at the front of the furnace over the dead plate whilst the feeding hole for the raw refuse is situated at the back of and above the furnace. By these means the gases from the raw refuse must pass, on their way to the main flue, over the hottest part of the furnace and through the flue opening in the red-hot reverberatory arch. By means of the forced draught, a temperature of from 1,500° to 2,000°, as tested by a thermoelectric pyrometer, is attained in the main flue. Cast-iron boxes are provided at the sides of the furnaces, and through these the forced draught is conveyed on its way to the fire grate. The boxes are also designed to prevent the adhesion of clinker to the side walls of the cells and so to preserve the brickwork.

The standard arrangement for a modern Manlove-Alliott top-fed destructor is designed on the "continuous hearth" principle whereby the furnace gases pass from cell to cell on their way to the combustion chamber, thus ensuring a uniform temperature and minimising the cooling down effect when fresh refuse is charged into the furnaces. A joint destructor and sewage pumping scheme has been installed by the Borough of Guildford and the Rural District Council of Hambledon, in which sewage is raised by pneumatic ejectors worked by steam from the refuse. There are four cells of the top-feed type arranged with two water-tube boilers on the Wood and Brodie "Unit" system. Each boiler is sandwiched between a pair of cells, and the high-temperature gases pass immediately into contact with the boiler heating surface. There are eight ejector stations, in each of which two ejectors work as a pair, arranged so that both ejectors cannot be filling or discharging at the same time. The ejectors are of the Alliott and Philips's automatic improved type.

Warner's destructor (the "Perfectus") was similar to Fryer's in general arrangement, but was provided with special charging hoppers, dampers in flues, dust-catching arrangements, rocking grate bars, and other improvements. The refuse was tipped into feeding-hoppers, consisting of rectangular cast-iron boxes over which plates were placed to prevent the escape of smoke and fumes. When refuse was fed into the furnace a flap door controlled by a lever was thrown over, the contents of the hopper dropped on to the sloping fire-brick hearth beneath, and the door at once closed again to prevent the admission of cold air into the furnace as far as possible. The cells were each 5 ft. wide by 11 ft. deep. The rear portion consisted of a fire-brick drying hearth, and the front of rocking grate bars upon which the combustion took place. The amount of refuse consumed varied from five to eight tons per cell per 24 hours.

The Meldrum "Simplex" destructor produced good steam rates

ing results and was first installed at Rochdale, Hereford, Darwen, Nelson, Plumstead and Woolwich. Cells have also been erected at Burton, Hunstanton, Blackburn, Burnley, Cleckheaton, Lancaster, Sheerness and Weymouth. This destructor differs from those previously described in general arrangement. The fire-grates are placed side by side without separation except by dead plates, but, in order to localize the forced draught, the asphalt is divided into parts corresponding with the different grate areas. Each asphalt is closed airtight by a cast-iron plate, and is provided with an airtight door for removing the fine ash. Two Meldrum steam-jet blowers are provided for each furnace, supplying any required pressure of blast up to 6 in. water column. The pressure usually used is about 1½ to 2 inches. The furnaces are designed for hand-feeding from the front, but hopper-feeding can be applied if preferred. The products of combustion are led from the back of each fire grate into a common flue leading to the boilers and to the chimney shaft, or are conveyed sideways over the various grates and a common fire bridge to the boilers or chimney. The heat in the gases, after passing the boilers, is still further used to heat the air supplied to the furnaces—the gases being passed through an air-heater or continuous regenerator consisting of a number of cast-iron pipes from which the air is delivered through the Meldrum blowers at a temperature of about 300°. At Rochdale, the Meldrum furnaces consumed from 53 lb to 66 lb of refuse per square foot of grate area per hour, as compared with 22½ lb per square foot in a low temperature destructor burning six tons per cell per 24 hours with a grate-area of 25 square feet. The evaporative efficiency varied from 139 lb to 187 lb of water (actual) per 1 lb of refuse burned, and the average steam pressure was about 114 lb per square inch.

The Beaman and Deas destructor was installed at Warrington, Dewsbury, Leyton, Canterbury, Llandudno, Colne, Streatham, Rotherhithe, Wimbledon, Bolton and elsewhere. At Leyton, which, at the date when this destructor was installed, had a population of over 100,000, an eight cell plant dealt with house refuse and filter press cakes of sewage sludge from the sewage disposal works adjoining. Each cell burnt about 16 tons of the mixture in 24 hours and developed about 35 h.p. continuously, at an average steam pressure in the boilers of 105 lb. The essential features of this destructor include a level fire-grate with ordinary type bars spaced only 3½ in. apart, a high temperature combustion chamber of about 2,000° at the back of the cells, a closed asphalt with forced draught, provision for the admission of a secondary air supply at the fire-bridge, and a fire-brick hearth sloping at an angle of about 52°. The forced draught is supplied from fans at a pressure of from 1½ to 2 in. of water gauge, and is

FIG 2—LONGITUDINAL SECTION OF REFUSE DISPOSAL PLANT OF THE NEW DESTRUCTOR COMPANY WITH REFUSE SCREENING PLANT
The refuse is delivered to 'refuse receiving hopper' then raised by 'dragbar conveyor' to the 'picking and screening table.' After sorting and screening the 'tailings' from the refuse are passed on to the 'charging platform' over the destructor cells where the material is burnt to an innocuous clinker.

controlled by means of baffle valves worked by handles on either side of the furnace. The heat from the cells is used in conjunction with a water-tube boiler such as the Babcock and Wilcox, and the gases on their way from the combustion chamber to the main flue pass three times between the boiler tubes. The grate area of each cell is 255q ft and the consumption varies from 16 to 20 tons of refuse per cell per 24 hours.

The Heenan destructor has been in use for over 25 years and a large number of installations have been erected in many of the largest cities throughout the world, including Birmingham, Glasgow, London, Leeds, Brussels, Paris, Rotterdam, Leningrad, New York, San Francisco, Montreal, Melbourne, Singapore, Edinburgh, Coventry, and many other places. The essential features of the Heenan System (fig 1) include a continuous furnace chamber with divided ashpits, air heater or regenerator, combustion and gas mixing chamber, steam generator, forced draught supply with efficient air regulation and a ventilation system.

The cells may be designed for hand feed under the direct control of the eye and hand of the stoker, either on the front-feed or back-feed system, or, where preferred, a system of mechanical charging and clinkering is installed. Mechanical clinkering has involved a change in grate design, and what is known as the trough-gate has been largely employed in the Heenan system. The advantages claimed are perfect combustion and the maintenance of a regular temperature and boiler pressure during the process of feeding and clinkering, freedom from dust and a minimum of labour in the clinkering operations, the production of a hard clinker practically free from carbon, and a general cleanliness and expedition in the clinkering operations.

By means of the air-heater or regenerator system (placed in the path of the gases after these have passed through the boiler) employed with these furnaces, the thermal efficiency of the furnace is improved, excess of air in the cells is avoided, and more steady and better steaming results are obtained. Those destructors fitted with top-feed are either charged by container feed, skip feed, or feed by conveyor. The mechanical control of the doors permitting the fall of the refuse into the furnace chamber may be by hand operation from the clinkering floor, hydraulic operation with ram cylinders on platforms at the level of the top charging doors, or electric motors may be used for the opening and closing of the doors controlled from the clinkering floor.

Furnace doors are air-cooled. When clinkering, provision is made by means of an asbestos preparation to seal the doors to prevent the escape of fumes into the building. During the three years the Coventry Heenan plant was under observation, over 2 lb

of steam at 160 lb pressure was produced for every 1 lb of refuse burnt, and in colliery districts as much as 4 lb of steam per 1 lb of refuse have been developed from the refuse.

In the London metropolitan area an important installation of the Heenan system was installed at Ilford in 1916, embodying mechanical charging and clinkering accessories. The plant consists of two three-grate (trough-type) units, each unit comprising three mechanically charged and clinkered grates, one Babcock and Wilcox water tube boiler of 200 lb per square inch working pressure, one Foster superheater, three electrically operated top-charging doors with frames, shafting, drums, pulleys and wire ropes complete, one Heenan fan and engine for forced draught, and two electric cranes for lifting the refuse skips. The steam produced is used to drive generators in an adjoining station. The average rate of evaporation per hour, from and at 212° per square foot heating surface of boiler, under test, was 3.9 lb. The average rate of evaporation per 1 lb of refuse burnt (from and at 212°) was 1.82 lb, and the steam pressure 155.8 lb per square inch. The temperature of the combustion chamber was—maximum 2,462°, minimum 1,886°.

At a modern installation at Birmingham (Brookvale road depot) a specially designed suction plant was installed to collect waste paper from the end of the conveying belts, and to deliver it free of dust, to baling presses. To facilitate clinker handling, a mono-rail or overhead railway, with skips equipped with raising and lowering gear, provides convenient means of transporting the clinker to the cooling area or to the clinker plant.

The Heenan system had been largely used on the Continent, where some of the largest and best equipped installations are to be found. The plant erected at Rotterdam (Holland) in 1912 is a good example.

The refuse disposal plants of the New Destructor Co include designs on the improved Horsfall and Sterling types. A typical plant is illustrated in fig 2 showing the handling and path of the refuse from the time it is delivered to the destructor works until its reception into the furnaces. The cells are of modern continuous grate high-temperature type, and equipped for good steam-raising results. The Horsfall Poplar plant yields 700 h.p. from the combustion of the refuse, the power being used for generating electric current. The evaporation per 1 lb of refuse burnt (from and at 212°) is about 1.5 lb of water. The Mersey Dock and Harbour Board, Liverpool, use a Horsfall plant yielding 360 h.p., for lighting, clinker treatment, etc., the capacity of five cells being 130 tons of refuse per 24 hour day. Sterling plants are used at Sydney (N.S.W.), Zurich, Colombo, Pittsburgh

FIG 3—SIDE ELEVATION OF MILLAR'S CLINKER CRUSHING, SCREENING AND GRADING PLANT FOR THE ECONOMICAL PREPARATION OF DESTRUCTOR CLINKER BEFORE ITS USE IN THE MANUFACTURE OF ASPHALT

(U.S.A.), Berkeley (U.S.A.), and Toronto (Canada). The Colombo plant is a six-cell Horsfall back-feed type with continuous grate, each cell has a grate area of 3950 ft. and is capable of burning ten tons per 24 hours. Forced draught is supplied by two positive blowers of the Roots pattern, exhausted through a galvanized iron overhead main with its intake in the hoppers. The foul gases from the refuse are thus drawn over with the cold air and forced through the regenerative air heater and through underground ducts to the front of the furnace blocks. A 6 in. cast-iron pipe is built into these ducts and connected to the side boxes for delivering the heated air to the underside of the grate bars.

Clinker asphalt machinery for the manufacture of road surfacing material is also provided, when required, in connection with Horsfall and Sterling furnaces. At an installation at Abertillery the cost per square yard of finished road including 2½ in. base or binder course with a 1 in. surfacing carpet costs about 7s. 3d. per square yard. Clinker asphalt plants are also in use at Woolwich and Hendon, and a complete plant is being erected at Walthamstow.

Beast-cremating Chamber.—This installation includes two beast-cremating chambers to enable cattle, horses, dogs, etc., to be disposed of in the event of cattle murrain breaking out in the city. At the top of the chambers are large cast-iron doors lined with fire bricks. The doors are fitted with a water seal to prevent hot gases blowing out. Carcasses are hoisted by pulley blocks mounted on a trolley fixed to steel joists so placed as to enable the beast to be lifted from the clinkering floor, traversed over the top of the furnaces to the centre of the cremating chamber, and dropped in by cutting a rope to avoid handling.

Destructor Records and Tests.—To judge correctly of the true performance of a destructor installation it is necessary to take careful observations and tests over long periods. Reliable records of every-day working throughout the whole year are necessary to gain a true knowledge of the performance of the plant. For such tests the destructor station should be provided with a road platform weigh-bridge, water meter, a pyrometer and, if possible, a carbon-dioxide recorder. The principal data to be noted include the weight and description of refuse burned, the quantity of water evaporated in destructor fired boilers, the average steam pressure, the weight of clinker and dust produced, the temperature in the combustion chamber and settings, and the percentage of carbon-dioxide in the flue gases. In order to determine the all-round efficiency of an installation, the leading facts to be ascertained from these data are the weight of refuse burnt per square foot of grate area, the water evaporation per 1 lb. of refuse consumed from and at 212°, the average temperature of the combustion chamber, the average carbon-dioxide gas analysis, the percentage of steam required to operate the de-

structor and its accessory plant, and the percentage and quality of clinker compared with the weight of refuse consumed.

Temperatures in the combustion chamber may be obtained by the use of the Féry radiation pyrometer, after the boiler by a mercury pressure pyrometer, and other temperatures by the mercury expansion thermometer. Other instruments used in connection with destructor tests are the Meyland-D'Arsonval galvanometer, and the Chatellier resistance pyrometer and galvanometer, as made by the Cambridge Scientific Instrument Co., Ltd. The continuous record of the chemical composition of the gases in the combustion chamber may be taken by means of the Simmance and Abady CO₂ recorder.

The higher the percentage of carbon-dioxide passing away in the gases the more efficient the furnace, provided there is no formation of carbon-monoxide; the presence of which would indicate incomplete combustion. The theoretical maximum of carbon-dioxide for refuse burning is about 20%, and, by maintaining an even clean fire, by admitting secondary air over the fire, and by regulating the dampers or the air-pressure in the ashpit, an amount approximating to this percentage may be attained in a well designed furnace if properly worked. If the proportion of free oxygen (i.e., excess of air) is large, more air is passed through the furnace than is required for complete combustion, and the heating of this excess is clearly a waste of heat.

Capital Costs and Working Expenses.—The capital cost of a destructor installation will depend very largely upon the local conditions, situation and nature of the site. In addition to the customary destructor buildings, cells, charging and clinkering machinery, brick settings, chimney shaft, inclined approach roadway, water supply, drainage, light, etc., a modern installation also usually comprises screening machinery for the removal of dust up to about ½ in to ¾ in gauge, power-driven elevators, sorting conveyor, electro-magnetic separators, clinker crusher and grading machinery, mortar mills, tin baling press, mess room and spray room, foreman's cottage, office, workshop, weigh-bridge, necessary road and yard formation, electric lighting and other accessories. The writer has had recent occasion closely to investigate the capital cost of such an installation for erection in Kent, capable of dealing with about 72 tons of refuse per 24 hours, and the inclusive cost based on quotations received, was estimated at £19,700 including a 150 h p Lancashire boiler, a 40 h p horizontal engine, and a five-kilowatt electric lighting set, all comprised within destructor buildings built with steel stanchions, 14 in. piers and 9 in. plain brick panels.

As regards the working expenses of dealing with the refuse by destructor, the average cost per ton of refuse, based on data from 20 towns in the south of England, was found to be 7s. 4½d. exclusive of loan charges. On a large portion of this class of

FIG. 4—SIDE ELEVATION OF MILLAR'S CLINKER ASPHALT PLANT FOR THE CONVERSION OF DESTRUCTOR CLINKER INTO ASPHALT FOR ROADWAYS

plant the depreciation and wear and tear are considerable. The loan period would therefore be relatively short, say from ten to 15 years only. Loan charges may amount to about 4s per ton, under present conditions of high costs of building and machinery, on a complete scheme as outlined above. In view of the high temperature at which the cells work they would probably require relining within a period of ten years.

As regards labour required, stokers, with hand fed plants, may deal with from five to six tons of refuse per man per eight-hour shift. For burning 50 tons of refuse per day of 16 hours four men per eight-hour shift would be required for stoking and firing. Extra labour would be needed for outside work such as clinker crushing, mortar making and other such work.

General Arrangement of Station.—In the general arrangement of a destructor station the cells are placed either side by side, with a common main flue in the rear, or back to back with the main flue arranged in the centre and leading to a tall chimney-shaft. The heated gases on leaving the cells pass through the combustion chamber into the main flue, and thence go forward to the boilers, where their heat is absorbed and utilized. Forced draught, or in many cases, hot blast, is supplied from fans through a conduit commanding the whole of the cells. An inclined road way, of as easy gradient as circumstances will admit, is provided for the conveyance of the refuse to the tipping platform, from which it is fed, either by hand or mechanically, through feed-holes into the furnaces. In the installation of a destructor, the choice of suitable plant and the general design of the works must be largely dependent upon local requirements, and should be entrusted to an engineer experienced in these matters. The following primary considerations, however, may be enumerated as materially affecting the design of such works: (a) The plant must be simple, easily worked without stoppages, and without mechanical complications upon which stokers may lay the blame for bad results, (b) it must be strong, must withstand variations of temperature, must not be liable to get out of order, and should admit of being readily repaired, (c) it must be such as can be easily understood by stokers or firemen of average intelligence, so that the continuous working of the plant may not be disorganized by change of workmen, (d) a sufficiently high temperature must be attained in the cells to reduce the refuse to an entirely innocuous clinker, and all fumes or gases should pass either through an adjoining red-hot cell or through a chamber whose temperature is maintained by the ordinary working of the destructor itself at a degree sufficient to exclude the possibility of the escape of any unconsumed gases, vapours or particles. The temperature may vary between 1,800° and 2,000°.

Modern practice favours the continuous hearth principle whereby the furnace gases pass from one cell to another on their way to a common combustion chamber, (e) the plant must be so worked that while some of the cells are being recharged, others are at a glowing red heat, in order that a high temperature may be uniformly maintained, (f) the design of the furnaces must admit of clinkering and recharging being easily and quickly performed, the furnace doors being open for a minimum of time so as to obviate the rush of cold air to lower the temperature in the main flues, etc., (g) the chimney draught must be assisted with forced draught from fans or steam jet to a pressure of 1½ in. to 2 in. under grates by water-gauge, (h) where a destructor is required to work without risk of nuisance to the neighbouring inhabitants, its efficiency as a refuse destructor plant must be primarily kept in view in designing the works, steam-raising being regarded as a secondary consideration, (i) where steam power and a high fuel efficiency are desired a large percentage of carbon-dioxide should be sought in the furnaces with as little excess of air as possible,

FIG. 5—DIAGRAM OF THE INSIDE OF A DESTRUCTOR DESIGNED TO DISPOSE OF REFUSE BY BURNING AND AT THE SAME TIME UTILIZE THE REFUSE AS FUEL TO DEVELOP STEAM POWER AND OTHER USEFUL SERVICES

and the flue gases should be utilized in heating the air-supply to the grates, and the feed water to the boilers, (j) ample boiler capacity and hot-water storage feed-tanks should be included in the design where steam-power is required.

Clinker Asphalt Plants.—The cells at the Brighton destructor works have been reconstructed by Messrs Heenan and Froude, Ltd., of Worcester, and a modern clinker asphalt plant installed. By means of this the destructor clinker is crushed, graded and mixed for use as an asphalt carpet or surfacing for roadways. This plant is illustrated in figs 3 and 4. Where there is a suitable outlet

for the manufactured product, such a plant is found to be a serviceable addition to a destructor installation, and affords a satisfactory means of using large quantities of clinker. The equipment consists of two sections—a crushing, separating, screening, grading and storage section, and a drying, heating and mixing section for the manufacture of asphalt from the prepared clinker.

The amount of clinker produced in Great Britain ranges from 20% to about 35% and it is important, financially, that suitable outlets should be made available for its use. In addition to asphalt making, it may be used in making clinker bituminous grout for carnegeways, for tarmacadam work, for making concrete building blocks by hand-operated machines or by hydraulic plants. Paving slabs, kerbs and channels may also be made from the crushed and graded clinker. Other uses include the bedding of street paving with the crushed material, the making of mortar

FIG 6—DIAGRAM OF THE INCINERATOR A TYPE OF DESTRUCTOR

for building, and the bottoming of roads and footways.

The carbon content of the clinker is an indication of the efficiency of the combustion in the cell, and should always be low. The usual accessories for dealing with clinker include crushing, elevating and grading machinery, paving slab presses and machines, clinker concrete block and brick making machines, mortar mills and asphalt plant. At the Coventry destructor the clinker represents about 25% of the refuse, and some 3,000 tons of clinker per annum are utilized for slab making, mortar making, tarmacadam work, for road foundations and similar requirements.

Use of Surplus Heat.—In order to render the refuse and gases therefrom perfectly innocuous and harmless, the modern high-temperature destructor must be worked at a temperature of not less than from 1,800° to 2,000°. The great heat thus developed has naturally suggested its utilization for steam production, and, where suitable outlets exist for its use, a reasonable addition to expenditure on plant and labour is justified. The actual calorific value of refuse varies widely in different places and also during different seasons of the year, but as a general average, with a suitably designed and well managed plant, an evaporation of 1 lb of water per 1 lb of refuse burned is a result readily attainable, and one which affords a basis of calculation which engineers may adopt in practice. The evaporative results obtained depend also upon the industry and skill of the stokers as well as on the quality of the refuse. Many destructor steam-raising plants give considerably higher results than those named above, and evaporations approaching 2 lb of water per 1 lb of refuse are met with under favourable conditions. In the coal-mining districts of Rhondda and Pontypridd evaporations from and at 212° of 4.15 lb and

3.47 lb of water per 1 lb of refuse are recorded. From long experience it may be accepted, therefore, that the calorific value of unscreened house refuse varies from 1 to 2 lb of water evaporated per 1 lb of refuse burned, and, taking the evaporative power of coal at 10 lb of water per 1 lb of coal, this gives for domestic house refuse a value of from one-tenth to one-fifth that of coal under normal conditions.

Destructor Electric Combinations.—In practice, however, when the electric energy is for the purpose of lighting only, difficulty has been experienced in fully using the thermal energy from a destructor plant owing to the want of adequate means of storage either of the thermal or of the electric energy. A destructor usually produces a fairly uniform amount of heat throughout the period of its work, while the consumption of electric lighting current is irregular and the maximum demand may be several times the mean demand. This difficulty may be greatly reduced by the provision of ample boiler capacity, or by the introduction of feed thermal storage vessels in which hot feed-water may be stored during the hours of light load. At the time of maximum load the steam boiler may be filled directly from these vessels which work at the same pressure and temperature as the boiler.

In cases where there is a day load, as for electric motive power purposes, equalizing the demand on both the destructor and the electric plant, the situation becomes much more favourable to the full utilization of the available surplus heat.

As regards sewage pumping, destructor installations of the New Destructor Co. are supplying power for this purpose at Gosport, Hampton, Leamington, Teddington, Worthing and other places, and a similar service is rendered by plants of Messrs. Manlove, Alliott and Co. at Guildford, Stroud and Cambridge, whilst the Heenan destructor affords power for sewage pumping at Portsmouth, Nuneston, Hanwell, Lincoln and elsewhere. (See *REFUSE DISPOSAL* for American practice.)

DESTUTT DE TRACY, ANTOINE LOUIS, COUNT:

see TRACY, ANTOINE LOUIS DESTUTT, COMTE DE

DE SYLVA, GEORGE GARD ("BUDDY") (1896-1950),

U.S. theatrical producer and song writer, was born in New York city, Jan. 27, 1896. De Sylva was the author of many popular song hits as well as producer of stage shows and motion pictures.

He teamed with George Gershwin to write the musical comedy *La, La, Lucille*, which was produced in 1919. Together they also wrote the songs "Somebody Loves Me" and "Do It Again." He collaborated with Victor Herbert on the musical *Orange Blossoms*, which contained the well-known song "A Kiss in the Dark."

He also wrote the books for such hit reviews as *Sally*, *Ziegfeld Follies of 1921*, six editions of *George White's Scandals*, *Follow Through*, *Three Cheers*, *Good News* and others.

Many of the 500 popular songs with which De Sylva was identified were composed in collaboration with Ray Henderson and Lew Brown. One of these was "Sonny Boy," written for Al Jolson, of which more than 1,500,000 copies were sold.

De Sylva produced five of Shirley Temple's pictures, *The Little Colonel*, *The Littlest Rebel*, *Captain January*, *Poor Little Rich Girl* and *Stowaway*. He also produced *Bachelor Mother*, starring Ginger Rogers.

He returned to New York as a stage producer in 1939, producing *Dr. Barry Was a Lady*, *Panama Hat* and *Louisiana Purchase*. He was executive producer of the film *For Whom the Bell Tolls*.

De Sylva died in Hollywood, Calif., July 11, 1950.

DE TABLEY, JOHN BYRNE LEICESTER WARREN, 3rd Baron (1835-1895). English poet, eldest son of George Fleming Leicester (afterward Warren), and Baron de Tabley, was born on April 26, 1835, and died at Ryde on Nov. 22, 1895. He was educated at Eton and Christ Church, Oxford, where he

took his degree in 1856 with second classes in classics and in law and modern history

In the autumn of 1858 he went to Turkey as unpaid attaché to Lord Stratford de Redcliffe and two years later was called to the bar. In 1871 he removed to London, where he was a close friend of Tennyson for several years. From 1877 till his succession to the title in 1887 he lived in complete seclusion, but in 1862 he returned to London and enjoyed a sort of renaissance of reputation and friendship.

De Tablay was at one time an authority on numismatics, he wrote two novels, and also published *A Guide to the Study of Book Plates* (1880). The fruit of his careful researches in the science of botany was printed posthumously in his elaborate *Flora of Cheshira* (1896).

From time to time he published volumes of verse under various pseudonyms. On the publication of *Philoctetes* in 1866 De Tablay met with wide recognition. *Philoctetes* bore the initials "M.A." which were interpreted as meaning Matthew Arnold. He at once disclosed his identity.

In 1867 he published *Orestes*, in 1870 *Rehearsals* and in 1873 *Searching the Net*. These last two bore his own name, John Leicester Warren. *The Soldier of Fortune* (1876), a drama on which he had bestowed much careful labour, proved a complete failure. The success of his *Poems, Dramatic and Lyrical* (1893) encouraged him to publish a second series in 1895, the year of his death.

His posthumous poems were collected in 1902. The characteristics of De Tablay's poetry are pre-eminently magnificence of style, derived from close study of Milton, sonority, dignity, weight and colour. He was always a student of the classic poets and drew much of his inspiration directly from them.

See a sketch by Sir Edmund Gosse, in his *Critical Kit Kats* (1896).
DETAILLE, (JEAN BAPTISTE) EDOUARD (1848-1912), French painter, was born in Paris on Oct. 5, 1848, and died there on Dec. 23, 1912. Using a technique of literal exactitude based on that of J. L. E. Meissonnier, whose studio he at first frequented, he painted anecdotal military subjects such as "Le Régiment qui passe" (1873). His most characteristic works, burdened with legend and sentiment, deal with Napoleon I and his armies. Among these are "Le Réve" (1888, City of Paris collection) and "L'Oeil du maître" (1897), but he later painted military scenes of his own times especially of the 1870-71 war. He visited Algeria, England and Russia, working for the prince of Wales and Tsar Alexander III. After 1891 he produced lifelike works such as "Les Victimes du devoir", a rare departure from military subjects, it depicts firemen at work. Detaille was also a gifted actor.

DETAINDER see DESTINUE
DETECTIVE STORIES see MYSTERY STORIES
DETECTOR, that part of a radio circuit whose function is to pick up or detect the electric oscillations which are set up in the antenna ($q \nu$) by the electromagnetic vibrations. (See WIRELESS TELEGRAPHY)

As used in a radio receiving apparatus it is connected to a circuit-carrying current of radio frequency and translates the radio-frequency power into a form suitable for the operation of an indicator. This translation may be effected either by the conversion of the radio frequency power into some other form or by the control of local power.

The indicator may be a telephone receiver, loud speaker, relaying device, tape recorder, etc. The most common type of detector is a vacuum tube operated on a nonlinear portion of its characteristic curve, thereby converting a modulated radio-frequency current into a modulated direct current.

DETERDING, SIR HENRI WILHELM AUGUST (1866-1939), Dutch oil executive and director general from 1902 to 1936 of the Royal Dutch Oil company. He was born in Amsterdam on April 19, 1866.

He left school at the age of 16 to join the staff of the Twentsche bank in Amsterdam, but after six years of drudgery as a clerk he

decided to seek his fortune in the East Indies.

In 1888 he was a bookkeeper at Belwan, in North Sumatra, for the Nederlandsche Handels Mij, the next year he was in agent for the trading company at Medan, and the year following at Penang.

In May 1896 he joined the Royal Dutch Oil company, then a comparatively small organization which had been founded six years before. Deterding advanced rapidly and expanded the company until it had storage outlets in many important Asian ports. A year after he became director general he formed the Asiatic Petroleum company, which immediately challenged the Standard Oil company for control of the rich oil markets in the far east. Deterding then extended his operations to Rumania, Russia, Egypt, South America and, in 1908, to the United States.

The company he originally founded in Oklahoma became the Rovana company and later the Shell Oil company.

He retired in 1936 from active direction of his far flung oil empire. Two years before he had published his autobiography *An International Oilman*, a work which served to dispel the public notion of him as a legendary giant of international finance.

Deterding, who was a knight of the British empire, died on Feb. 4, 1939, at St. Moritz, Switzerland.

DETERGENTS AND WETTING AGENTS Ordinary soaps are sodium and sometimes potassium salts of the fatty acids with from 12 to 18 carbon atoms per molecule. They are the most universal and simplest of detergents and wetting agents, and are used for cleaning all sorts of surfaces and for enabling a cleaning liquid, such as water, to wet a surface or to penetrate a porous body such as a piece of cloth. The necessity of using a detergent or wetting agent is seen immediately if one attempts to wash a greasy dish with water.

Ordinary soaps leave a sticky residue of lime soap on bathtubs and towels when used with hard water because the calcium and magnesium soaps formed are insoluble. Likewise, if the attempt is made to use soaps in acid solution, the soap is decomposed with the formation of insoluble acid soaps and fatty acids.

Cleaning materials have long been sought that do not possess the limitations of ordinary soaps or that surpass them in one or more respects. The need for these is greatest throughout the textile industry, whether one is dealing with cotton, silk, wool or some synthetic fabric such as rayon. It was first felt in connection with dyeing, in which the dye solution must wet and evenly penetrate the fabric.

In the middle of the 19th century Turkey red oil came into use to carry the dye (Turkey red) by means of modified soaps made from an oil such as castor oil that had first been treated with concentrated sulphuric acid.

It was not until after 1932 that the chemical industry began to supply a series of detergents that could be used, without decomposition, with hard water or even in the presence of an acid. The first of these synthetic detergents or wetting agents were closely modelled upon soaps. A soap consists of an oily part resembling a hydrocarbon in composition and structure together with a polar or soluble part that brings it into solution in water, in the simplest synthetics only the nature of the polar part was altered. The first examples were the familiar sodium alkyl sulphates. Subsequently, thousands of patents described large classes of synthetic detergents, some of very complicated structure and possessing special uses.

All detergents which, like soaps, are sodium or potassium salts are anion active, that is to say, they owe their detergent action to the distinctive properties of their negative ions (viz., anions). Conversely, all detergents which are chloride, bromide, iodide or acetate salts, and which owe their detergent action to large positive organic ions, are cationic active. Examples are the chlorides of amines containing from 12 to 18 carbon atoms per molecule. A third important class of detergents consists of non ionic compounds, which are not salts. Many of them are derived by condensing ethylene oxide with organic substances such as phenols or fatty acids. They are unaffected by hard water, salts, acids and mild alkalis.

Detergency involves the replacing of dirt with an infinitesimal

film of detergent and the carrying away of the dirt in solubilized, emulsified or suspended form.

Detergents derived by combining kerosene with sodium benzene sulphate were largely used throughout World War II for washing in sea water. Detergents are invaluable as germicides, insecticides, emulsifiers, spreaders, foaming and antifoaming agents, additives in foods and in drilling muds, as aids in the conversion of the proteins of milk, chicken feathers and soybeans into fibres which may be spun into textiles, as carriers for insoluble dyes, and as additives to control the adhesion of paints, lacquers or bituminous coatings on roads. They are produced in amounts almost comparable with that of soap although many commercial soaps, to meet this rivalry, were improved by incorporating phosphates in them. (See Soap.)

DETERMINANT, an algebraic expression associated with a square array whose elements are numbers or other numberlike mathematical quantities. A determinant of n rows and n columns is called an n -rowed determinant, or a determinant of order n . Let the element in its i th row and j th column be designated by the symbol a_{ij} . Then the accepted notation for the array or matrix of elements is

$$A = (a_{ij}) \quad (i, j = 1, \dots, n),$$

and for the determinant of this square matrix A is

$$|A| = |a_{ij}|$$

Determinants of orders one and two, respectively, are defined as follows

$$|a| = a, \quad \begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc$$

Thus a number a defines a one by one matrix (a) whose determinant is the number a .

Determinants of order n are defined as follows. Let $A = (a_{ij})$ be an n -rowed square matrix. The diagonal term of $|A|$ is the product $d = a_{11}a_{22}\dots a_{nn}$. If P is the permutation which carries the integers $1, 2, \dots, n$ into the rearrangement i_1, i_2, \dots, i_n there is a corresponding product $d_P = a_{1i_1}a_{2i_2}\dots a_{ni_n}$. There are $n! = n(n-1)(n-2)\dots 3 \cdot 2 \cdot 1$ permutations P on the first n integers and so there are $n!$ products d_P . These are all the possible products obtainable by selecting one and only one element from each row and column of A . Apply P to the so called alternating function $f = f(x_1, x_2, \dots, x_n) = (x_1 - x_{n-1})(x_2 - x_{n-2})\dots(x_{n-1} - x_2)$ and obtain the function $f_P = f(x_{i_1}, x_{i_2}, \dots, x_{i_n})$. It can be shown that $f_P = \epsilon_P f$ where $\epsilon_P = +1$ or -1 . Add the $n!$ terms $\epsilon_P d_P$ and define the n -rowed determinant $|A|$ to be the sum of these $n!$ signed products.

This definition appears to have been formulated first by Gottfried W. Leibnitz in a letter which he wrote to Guillaume F. L'Hôpital in 1693. The discovery does not seem to have had any influence, and determinants did not come into general use until they were rediscovered by G. Cramer, who published this same definition in 1750. The vertical bar notation was first introduced by Arthur Cayley in 1841.

Determinants arise in the study of the solution of a simultaneous system of n linear equations in n unknowns. For example, consider the system

$$\begin{aligned} ax + by &= e, \\ cx + dy &= f, \end{aligned}$$

in which the letters a, b, c, d stand for known quantities and x and y are to be determined. We may eliminate y by subtracting b times the second equation from d times the first equation and obtain $(ad - bc)x = ed - bf$. Hence if $D = ad - bc$ is not zero, we can express x as the quotient of two determinants. Indeed,

$$x = \frac{\begin{vmatrix} e & b \\ f & d \end{vmatrix}}{D}, \quad y = \frac{\begin{vmatrix} a & e \\ c & f \end{vmatrix}}{D}$$

Similarly, consider a system of n linear equations of the form

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \dots + a_{1n}x_n &= k_1, \\ a_{21}x_1 + a_{22}x_2 + \dots + a_{2n}x_n &= k_2, \\ &\vdots \\ a_{n1}x_1 + a_{n2}x_2 + \dots + a_{nn}x_n &= k_n, \end{aligned}$$

with $D = |a_{ij}|$ as the determinant of its coefficients. Define K_i to be the determinant obtained by replacing the i th column of D by the column of constants k_1, k_2, \dots, k_n . Then $Dx_i = K_i$. This is called Cramer's rule for the solution of linear equations. It implies that if $D \neq 0$ the system has the unique solution $x_i = K_i/D$.

Determinants are useful as an instrument by means of which systems of linear equations may be classified. Thus, in dealing with linear equations with $D = 0$, one possibility is that in which one k_i is not zero. Then there will be no values whatever satisfying all the equations. Criteria for deciding when systems of linear equations have solutions and how many of these solutions are independent can be obtained from the theory of determinants.

Expansions of Determinants—The array formed by the elements in r rows and r columns of a matrix A is an r -rowed square matrix whose determinant is called a minor of A . The minors of a determinant $|A|$ are merely the minors of the square matrix A . If r rows and r columns of an n -rowed square matrix A are selected the remaining $n-r$ rows and columns are thereby also selected. Thus every r -rowed minor of an n -rowed determinant $|A|$ determines an $(n-r)$ -rowed minor of $|A|$, and these two minors are said to be complementary minors of $|A|$.

Every element of a determinant $|A|$ may be regarded as a one-rowed minor of $|A|$ and the elements of $|A|$ then have complementary minors which are $(n-1)$ -rowed. If d_{ij} is the complementary minor of the element a_{ij} , we shall call the signed determinant, $k_{ij} = (-1)^{i+j}d_{ij}$, the cofactor of a_{ij} . If we multiply the elements of any row (or column) of $|A|$ by their cofactors, and add, the resulting sum is the determinant of A . For example,

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = a_{11} \begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} - a_{12} \begin{vmatrix} a_{21} & a_{23} \\ a_{31} & a_{33} \end{vmatrix} + a_{13} \begin{vmatrix} a_{21} & a_{22} \\ a_{31} & a_{32} \end{vmatrix}$$

The sum of the products of the elements of the i th row (column) by their cofactors is called the expansion of $|A|$ according to its i th row (column). The expansion of a determinant according to the elements of its first row may be used as an inductive definition of a determinant and provides an alternative basis of the theory of determinants. Note, finally, that the sums obtained by multiplying the elements of any row (column) by the cofactors of the elements of any other row (column) are all zero.

A generalization of the expansions given above is due to Pierre Simon Laplace and may be described as follows. Select any r rows of $|A|$. Compute all r -rowed minors with elements in these r rows. There are $C_{n-r} = n(n-1)\dots(n-r+1)(r-1)\dots 1$ such minors, where C_{n-r} is then the number of ways of selecting r columns from n columns. Multiply each of these r -rowed minors M_i by its complementary minor $M_{i,r}$ and prefix the sign $+1$ or -1 according as the sum of all of the r row subscripts and all of the r column subscripts of M_i are even or odd. The sum of these C_{n-r} signed products will be the determinant of A . The sum of the signed minors in r rows by the complementary minors of a different selection of r rows is zero. There are corresponding results on column expansions.

The Laplace expansions imply the following important consequence. Suppose that the matrix of a determinant has the form

$$A = \begin{pmatrix} B & O \\ C & D \end{pmatrix},$$

where B is an r -rowed square matrix, C has $n-r$ rows and n columns, D is an $(n-r)$ -rowed square matrix, and the symbol O represents an array with r rows and $n-r$ columns of elements all zero. Then $|A| = |B| |D|$. Matrices of this kind occur frequently in algebraic research. The main use of the result is that we can state that if $|A| \neq 0$ then $|B| \neq 0$ and $|D| \neq 0$ and conversely if $|D| \neq 0$ and $|B| \neq 0$ then $|A| \neq 0$.

Elementary Properties of Determinants—The computation of a determinant whose elements are numbers may be simplified

to a considerable extent by the use of certain properties of determinants. Suppose first that the rows of the matrix of a determinant are interchanged with the columns. Then the value of the determinant is unchanged. This law permits the restatement of any property given in terms of the rows of a determinant as a corresponding property in terms of columns. The row properties are the following:

If two rows of a determinant are interchanged, the determinant is changed in sign only.

If a row of a determinant is multiplied by a number k the determinant is multiplied by k .

A determinant is not changed in value if a multiple of any one of its rows is added to another row.

If two rows of a determinant are proportional or one row consists of elements all zero, the value of the determinant is zero.

Let $|A|$, $|B|$ and $|C|$ differ only in the i th row and suppose that every element of the i th row of C is the sum of the corresponding elements in the i th row of A and B . Then $|A| + |B| = |C|$.

The properties above are not only useful for the computation of determinants but are also of fundamental importance in the theory of matrices.

Special Properties — Determinants may be used to determine whether or not two polynomial equations in one variable have a solution in common. Let the equations be

$$\begin{aligned} f(x) &= a_1x^m + a_2x^{m-1} + \dots + a_{m+1} = 0 \\ g(x) &= b_1x^n + b_2x^{n-1} + \dots + b_{n+1} = 0 \end{aligned}$$

Form the determinant of order $m+n+2$ given by

$$D = \frac{|A|}{|B|},$$

where A has $m+1$ rows, B has $n+1$ rows and we have the formulas

$$A = \begin{pmatrix} a_1 & a_2 & \dots & a_{m+1} & 0 & \dots & 0 \\ 0 & a_1 & a_2 & \dots & a_{m+1} & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \dots & 0 & a_{m+1} & 0 & \dots & 0 \end{pmatrix}, \quad B = \begin{pmatrix} b_1 & b_2 & \dots & b_{n+1} & 0 & \dots & 0 \\ 0 & b_1 & b_2 & \dots & b_{n+1} & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \dots & 0 & b_{n+1} & 0 & \dots & 0 \end{pmatrix}$$

The two equations will have a solution in common if and only if $D=0$. For example let $f(x)=x+x-2$ and $g(x)=x-1$. Then the expansions we have given may be used to show that

$$D = \begin{vmatrix} 1 & 1 & -2 & 0 & 0 \\ 0 & 1 & 1 & -2 & 0 \\ 0 & 0 & 1 & 1 & -2 \\ 1 & -1 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 \end{vmatrix} = -4 \begin{vmatrix} 1 & -1 & 0 \\ 1 & 0 & -1 \end{vmatrix} = 0$$

and the equations have a solution in common. The result was due to James J. Sylvester and is called Sylvester's dialytic method of elimination.

Another topic connected with the theory of equations is the subject of alternants. An alternant is an n -rowed determinant which is a function $d(x_1, \dots, x_n)$ such that the interchange of any two of the variables changes the sign of d . The alternating function $f(x_1, \dots, x_n) = (x_n - x_{n-1})(x_{n-1} - x_{n-2}) \dots (x_2 - x_1)$ which was used in the definition of determinants is expressible as an alternant, namely,

$$f(x_1, \dots, x_n) = \begin{vmatrix} 1 & x_1 & x_1^2 & \dots & x_1^{n-1} \\ 1 & x_2 & x_2^2 & \dots & x_2^{n-1} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & x_n & x_n^2 & \dots & x_n^{n-1} \end{vmatrix}$$

and this determinant is called the Vandermonde determinant of order n . Every alternant with polynomial elements has the alternating function as a factor. The discriminant δ of the equation $F(x) = (x-x_1)(x-x_2) \dots (x-x_n) = 0$, whose roots are x_1, \dots, x_n , is the square of the alternating function. The coefficients of δ are polynomials in the coefficients of $F(x)$ with integer coefficients. The importance of δ lies in the fact that formulas for computing it in terms of the coefficients of $F(x)$ are known and $F(x)=0$ has a multiple root if and only if $\delta=0$.

Symmetric and skew determinants are especially interesting. Since there may be symmetry with respect to a line or a point there are two kinds of determinants which possess symmetry. Those which are symmetric with respect to the centre are called centrosymmetric. The term "symmetric" is usually reserved for those determinants which are symmetric with respect to the main diagonal.

In a centrosymmetric determinant the $(n-r)$ th row coincides with the r th row read in reverse order. Every centrosymmetric determinant of even order $2m$ is expressible as a product of two determinants each of order m . A determinant is said to be skew centrosymmetric when every element is the negative of the element symmetrically placed with respect to the centre. Every skew centrosymmetric determinant of even order is expressible as the difference of two squares.

A symmetric determinant $|A| = |a_{ij}|$ is defined by the property that $a_{ij} = a_{ji}$ for $i, j = 1, \dots, n$. Determinants may be multiplied by the law for the product of matrices (see MATRICES) and so $|A| = |A| |A'| = |AA'|$, where A' is the result of interchanging rows and columns in A . The product AA' is symmetric and it follows that the square of every determinant is expressible as a symmetric determinant. The product $|A| |B'| = |AB'|$ of any symmetric n -rowed determinant $|A|$ by the square of any n -rowed determinant $|B|$ is expressible as the n -rowed symmetric determinant of the matrix product AB' . It is also true that any power of a symmetric n -rowed determinant is expressible as a symmetric n -rowed determinant.

A determinant $|a_{ij}|$ is called a skew determinant if $a_{ij} = -a_{ji}$. The diagonal elements are then all zero. Every skew determinant of odd order is zero. A skew determinant of even order is the square of a polynomial in its elements.

The adjoint of a determinant $A = |a_{ij}|$ is the determinant $|d_{ij}|$ where d_{ij} is the cofactor of a_{ji} . Then $|d_{ij}| = |a_{ij}|^{n-1}$. The adjoint of a skew determinant of even order is again skew.

See Thomas Muir, *The Theory of Determinants in the Historical Order of Development*, vol. 1-IV (London, 1906-20); A. A. Albert, *College Algebra* (New York, 1946). (A. A. AT)

DETERMINISM, in ethics, the name given to the theory that all moral choice, so called, is the determined or necessary result of previously existing mental, physical or environmental causes (Lat. *determinare*, to prescribe or limit). The doctrine of determinism is opposed to the various doctrines of free will, known as voluntarism, libertarianism, indeterminism, and is commonly regarded as more or less akin to necessitarianism and fatalism.

There are various degrees of determinism. It may be held that every action is causally connected not only externally with the agent's environment but also internally with his motives and impulses. In other words, if we could know exactly all these conditions, we should be able to forecast with mathematical certainty the course which the agent would pursue.

On this theory the agent cannot be held responsible for his action in any sense. It is the extreme antithesis of indeterminism or in determinism, the doctrine that a man is absolutely free to choose between alternative courses (the *liberum arbitrium indifferentiae*). Since, however, the evidence of ordinary consciousness almost always goes to prove that the individual, especially in relation to future acts, regards himself as being free within certain limitations to make his own choice of alternatives, many determinists go so far as to admit that there may be in any action which is neither reflex nor determined by external causes solely an element of freedom.

This view is corroborated by the phenomenon of remorse, in which the agent feels that he ought to, and could, have chosen a different course of action. These two kinds of determinism are sometimes distinguished by the terms "hard" and "soft" determinism.

The controversy between determinism and libertarianism hinges largely on the significance of the word "motive" indeed in no other philosophical controversy has so much difficulty been caused by purely verbal disputation and ambiguity of expression. How far, and in what sense, can action which is determined by motives be said to be free?

The scientific doctrine of evolution has gone far toward obliterating the distinction between external and internal compulsion, e. g., motives, character and the like. Insofar as man can be shown to be the product of, and a link in, a long chain of causal development, so far does it become impossible to regard him as entirely self-determined.

Even in his motives and his impulses, in his mental attitude toward outward surroundings, in his appetites and aversions, inherited tendency and environment have been found to play a very large part, indeed many thinkers hold that the whole of a man's development, mental as well as physical, is determined by external conditions.

In the Bible the philosophical-religious problem is nowhere discussed, but the Bible usually assumes the freedom of the human will. It has been argued by theologians that the doctrine of divine foreknowledge, coupled with that of the divine origin of all things, necessarily implies that all human action was foreordained from the beginning of the world.

Such an inference as this is, however, clearly at variance with the whole doctrine of sin, repentance and the atonement, as also with the doctrine of eternal reward and punishment, which postulates a real measure of human responsibility, impossible without free will.

For the history of the free will controversy, see the articles, FREE WILL, PREDESTINATION (for the theological problems), ETHICS, HISTORY OF.

DETINUE, in law, an action whereby one who has an absolute or a special property in goods seeks to recover from another who is in actual possession and refuses to redeliver them. (See CONTRACT, TORT.)

DETMOLD, the capital city of the former *Land* of Lippe, Ger., on the east slope of the Teutoburger Wald, 25 mi S of Minden, on the Herford Altenbeken line of the Prussian State railways. Pop. (1939) 23,314.

The Renaissance chateau of the princes of Lippe-Detmold (1550) is an imposing building nearly in the centre of the town, while at the entrance to the large park on the south is the New Palace (1708-18), enlarged in 1850. Detmold possesses a natural history museum, theatre, etc. Furniture, gloves, agricultural implements, etc., are made.

At a distance of about 3 mi to the southwest of the town of Detmold is the Grotenburg, with Ernst von Bandel's colossal statue of Hermann, or Arminius, the leader of the Cherusci. Detmold (Thatmelli) was in 783 the scene of a conflict between the Saxons and the troops of Charlemagne.

DETONATOR, device employing certain sensitive explosives, called initiating or primary, to cause explosion of other less sensitive materials, called high explosives. Mercuric fulminate ($g v$), lead azide ($g v$) and some organic diazo derivatives are used in the initiating charge of the detonators.

This charge is usually followed by a larger charge of a sensitive high explosive, such as tetryl or PETN, to enhance the initiating action of a detonator without employing a large quantity of a hazardous primary explosive. The charge of a detonator is usually contained in a thin walled copper or aluminum capsule sealed against moisture.

Detonators are manufactured in various sizes, numbered 1 to 8, to indicate the strength of the charge they contain. They may be exploded by heating electrically a thin bridge wire (of electric detonators) or by igniting the initiating charge (of blasting caps) by a fuse ($g v$). In some military fuses the detonator is exploded by the action of a primer.

Each high explosive requires a certain minimum size of detonator for a reliable initiation. In general, the less sensitive to percussion an explosive is (i. e., the safer it is to handle), the stronger is the detonator required to explode it. (See EXPLOSIVES.) (G B K)

DETROIT, a city of Michigan, U. S., fronting 12 mi along the Detroit river and covering an area of 140 sq mi, was founded and named by the French under the command of Antoine de la Mothe Cadillac July 24, 1701. Detroit ("City of the Straits") is strategically located on the Great Lakes. Across the river is

Windsor, Ont., a gateway to Canada. Because of the course of the Detroit river, Windsor lies south of Detroit. Detroit has a moderate climate with a mean average temperature of 48.6° F and an average rainfall of approximately 31.53 in., equally distributed throughout the year. Average humidity is 71%, altitude is 581 ft above sea level.

Population—In 1820 the population of Detroit was 1,422. By 1830 the population rose to 2,222 and to 9,102 by 1840. Better railroad service led to continued growth, and by 1850 the population was 21,019; it was 45,619 in 1860, 79,577 in 1870 and 285,704 in 1900.

The coming of the automobile and related industries gave the city its greatest increase in population. In 1900-30 more than 1,250,000 additional persons established residence in the city. In 1910 the population was 465,766, succeeding censuses were as follows: (1920) 993,678, (1930) 1,568,662, (1940) 1,623,452, (1950) 1,849,568.

The Detroit metropolitan district (Wayne, Oakland and Macomb counties) had 2,973,019 in 1950—an addition of more than 500,000 since 1940. There are two independent cities (Hamtramck and Highland Park) within the boundaries of Detroit. Each has a population of nearly 50,000.

Detroit is one of the most healthful cities in the United States, with a death rate in 1949 of only 8.2 per 1,000 inhabitants.

Industry, Commerce, Communications—Fur was the only commodity early Detroiters sold outside their own community. A few grist mills, soap factories and distilleries made products for local use in 1810; the total volume was approximately \$25,000 annually.

Around 1830 shipbuilding was a vital industry. By 1860 steam engines and other machinery manufactured in the Detroit area had increased the total volume of business to more than \$600,000 annually. By 1900 Detroit had a diversity of industries—foundry and machine shops, druggist preparations, stoves and furnaces, carriages, woodcrafts, meat packing and cigar making. About this time several men in these industries became interested in the French inventions of the internal combustion gas engine. In 1894 Charles King caused much excitement when he drove his first car down a Detroit street.

Others fostered this new development and the automobile industry was born and nurtured in Detroit. Pioneers in the field were Ransom Olds, Henry Leland, the Dodge brothers, W. C. Durant and Henry Ford. Ford's name and automobiles came to be almost synonymous. His first automobile was a two cylinder machine mounted on a light chassis geared to rubber-tired bicycle wheels.

Ford's outstanding contribution to the industry was the development of the assembly line in mass production. With 0.4% of the United States population in 1904, Detroit was making one-fifth of the nation's automotive products.

By mid-century Detroit was making one-half of the products of the country's largest industry. It also ranked at or near the top in U. S. production of pharmaceuticals, adding machines, foundry products, machine tool accessories, ranges and heating devices, paints and heavy chemicals. Other important industries include machinery, stampings, hardware, wirework, machine shop products, rubber products and electrical household appliances. About 1920 Detroit became a steel centre because of the availability of raw materials and the demands of its local industries for steel. The chemical industry in Detroit also prospered after discovery of a layer of rock salt 34 ft thick, 1,000 ft below the surface. The mine has about 60 mi of tunnels, and the supply is believed to be unlimited.

World War II brought more prime contracts for war materials to Detroit than to any other area in the United States. Reconversion to peacetime production was accomplished speedily.

The Michigan customs district ranked third in foreign trade in the United States at mid 20th century, with exports totalling \$653,300,000 during 1949. The Great Lakes waterway is the principal means for carrying on this trade, which accounts for \$1 out of every \$7 spent in the Detroit area. About 300 items are imported for use in the production of automobiles. Facilities es-

sential to international commerce are available in Detroit, which is a port of call for cargo boats including ocean going freighters operating on the Great Lakes. Passenger, cruise and excursion lines provide regular service.

There are nine major railroad systems operating out of the city. Seven commercial air lines use the facilities of Willow Run airport, City airport and Wayne County airport provide additional terminals for private passenger and freight carrying air lines. Four major bus lines serve the entire industrial area and connect with a nation wide system.

Within Detroit, the public transportation system operates over 1,200 route miles. Deliveries are made by more than 200 motor truck carriers throughout the U.S. and Canada. Trade with Canada is facilitated by two tunnels, a bridge and three railroad car ferries. There were 650,000 passenger cars and 70,000 privately owned trucks in use in the city in 1950.

Eleven AM and FM radio and three television stations were broadcasting from Detroit at mid 20th century. Three daily newspapers, the *Free Press*, *News and Times*, had a combined daily circulation of 1,302,000.

Detroit's rapid industrial growth has presented many problems, complicated by business booms, depressions and war. To meet them, better planning of production, low cost housing, slum clearance and labour management received the constant attention of civic leaders.

Industrial and civic groups co-operated on two major projects—a United Fund drive, whereby all agencies soliciting contributions concentrate their efforts into one sustained drive for funds, and a commission to study plans and obtain funds to expand the hospital facilities in the city. There were 60 hospitals in Wayne County at mid century.

Government—Detroit has a mayor-council, nonpartisan type of government. A new charter was adopted in 1918 whereby the mayor, city clerk, city treasurer and board of education are elected at large. The mayor has broad powers to appoint most of the administrative officials and commissions—board of assessors, board of health, city planning, public lighting, water, street railway, fire, public welfare, police and other commissions. The common council consists of nine members, elected at large. The councilman receiving the most votes at the election automatically becomes president of the council and acting mayor in the absence of that official.

After the federal government began its housing program in 1934, Detroit promoted and sponsored slum clearance and low-cost housing. Wide streets and expressways were built to accommodate the many private automobiles and buses that pour into the city from the outlying industrial and residential communities of River Rouge, Dearborn, Ecorse, Wyandotte, the Grosse Pointes, Lincoln Park, Melvindale, Allen Park, Inkster, Ferndale, Pleasant Ridge, Royal Oak, Bloomfield, Hazel Park, Berkeley, Roseville, East Detroit, St. Clair, Centerline and Birmingham.

Within the downtown loop are most of the city's largest office buildings, its great hotels, department stores and banks. The Penobscot building, 47 stories, is the tallest skyscraper. Largest office building outside the loop is the General Motors building in the new centre area. The financial and banking firms are centred around Griswold street. Many exclusive shops are to be found on Washington boulevard.

In 1950 municipal planning included a new civic centre, a river front drive and extended parking facilities in the downtown area. The civic centre is located on a 58.3 ac site along the Detroit river at the hub of the radial pattern of the city. The plan called for seven main buildings: Veterans' Memorial building (completed in 1950), city county building, civic auditorium, a convention hall, an exhibition area, a state building and a federal building. Many unsightly and antiquated structures were removed to provide space for this project.

Education—There were 251,897 regularly enrolled students in 1950, including 20,257 at Wayne university, which is part of the public school system. The physical plant totalled 270 school buildings, including 22 high schools and 10 trade schools. Parochial and private schools numbered 146, with 79,171 students enrolled.

Higher education is provided by Wayne university, University of Detroit, Marygrove college, Detroit Institute of Technology, University of Michigan extension service and Highland Park Junior college. Several private schools add fame to the community. Cranbrook Academy of Art, Edison Institute at Greenfield Village, and Merrill Palmer, a pioneer in the field of home economics.

Early in the history of Detroit such men as Father Gabriel Richard, John Monteith and Augustus Woodward recognized the vital need of free educational opportunities and directed their efforts toward promoting these advantages for Detroiters. In 1841 a bill was passed to establish free public schools for all children between the ages of 4 and 17. The board of education had 2 inspectors from each ward, or 12 men, and the mayor and a recorder as ex officio members, and the city was incorporated into one school district. This act was modified later, but the pattern remained much the same.

In 1918 an act provided for a board of education with seven members elected at large, a few at a time with no party designation. The board has entire charge of the public schools, with certain veto rights given to the mayor and appropriations subject to revision by the mayor and the common council.

A census taken every year of children of school age is the basis for appropriations from the primary school interest fund. When the foreign born were coming to Detroit in large numbers to work in the factories, the public schools set up night schools for instruction leading to citizenship, and from this a well rounded program of adult education developed. During World War II using these facilities, skilled workers were trained for war production in a short time.

Culture and Recreation—There are 22 branches to the Detroit Public Library. About 350,000 registered borrowers were drawing about 4,000,000 books annually at mid-20th century. The main library is located in the cultural centre, with the Detroit Institute of Arts, the Rackham Educational memorial, the Children's museum, the Detroit Historical museum and Wayne university near by. The Institute of Arts, a municipally owned museum, houses paintings, sculptures and decorative arts from prehistoric to the modern. The Children's museum contains mobile exhibits to assist in supplementing the current curriculum of the public schools.

Henry Ford's Greenfield Village and Edison museum are devoted exclusively to U.S. historical buildings, machines and products. There Thomas A. Edison is immortalized in the restoration of his Menlo Park laboratory. The village embodies 200 ac of historical buildings moved from their original sites and restored for posterity. There are approximately 1,100 churches of all denominations in Detroit.

Recreational facilities of the metropolitan area have been supplemented by Wayne county and the state of Michigan with parks, camping and picnicking sites, fishing and hunting sites, bathing beaches and amusement parks. Within the city of Detroit itself there were 46 parks at mid-century, covering 3,400 ac maintained by the city.

Belle Isle, a 1,000 ac island in the Detroit river, is notable for its beautiful drives, virgin forests, formal rose gardens, carousel tower, monuments and fountains, picnic and playground areas, bridge paths, golf course, artificial lakes, city zoo, casino, aquarium, bathing beach, botanical conservatory, outdoor theatre, yacht basin and private yacht clubs. Another large park is River Rouge park, comprised of 1,204 ac with many recreational provisions: a large municipal nursery, golf course, winter sports facilities and swimming pools. There are numerous neighbourhood block parks.

Convention hall is the scene of many annual events: a flower show, builder's show, automobile show, sports show and many trade shows. In 1948 an annual air show was organized by the various air minded groups of the city. Automobile and other industrial plants maintain visiting hours for tourists.

History—Fort Pontchartrain du Detroit was settled under the leadership of Antoine de la Mothe Cadillac. Cadillac was transferred to the governorship of Louisiana in 1710 and shortly after, hostilities broke out between the settlers and the Fox Indians of Wisconsin. From 1717 until the French and Indian War and the

end of French rule in North America, the residents of the fort devoted themselves to trade and agriculture. On Nov. 29, 1760, the fort surrendered, without resistance, to Maj. Robert Rogers of the British army. Under British control there was a decline in population and trade.

John Jay negotiated a treaty with England after the American Revolution, and the U.S. flag was raised over the fort. The national government recognized Detroit as a port of entry and representative government was established. The first post road was opened to Monroe, Mich., in 1801.

In Jan. 1802 the town of Detroit was incorporated. A land office was opened by the federal government in 1804. Congress created the Michigan territory, which included what are now Michigan, Wisconsin and a part of Minnesota, and in 1805 Detroit was made the capital of the territory.

The same year fire destroyed all but one building in the town, which was rebuilt on a plan submitted by Pierre Charles l'Enfant, the French engineer who designed Washington, D.C., the plan was of the same general radial pattern as the U.S. capital. Each citizen who had his home destroyed was awarded a larger lot, resulting in a city of openness. During the War of 1812 Gov. William Hull surrendered the town to English forces under suspicious circumstances. The attackers had met with no resistance. The British maintained their control of Detroit until the battle of Lake Erie on Sept. 10, 1813, when Lieut. (later Comm.) Oliver Perry defeated the British.

Detroit was incorporated as a city in 1815, but it was not until 1824 that the first mayor was elected—Gen. John R. Williams. The opening of the Erie canal in 1825 provided better communications with the east, and many pioneers sought land in Detroit and vicinity.

When Michigan was admitted to the union in 1837, Detroit became the capital and remained so until 1847, when the capital was moved to Lansing. Detroit was an important terminal for the Underground Railroad for runaway slaves transported to Canada before the Civil War.

Stark, *City of Destiny* (1941); John C. Lodge, *I Remember Detroit* (1949); John R. Stewart, *Places and Figures about Detroit* (1950). (L.F.M.)

DETROIT LAKES, a city of Minnesota, U.S., and seat of Becker county, in the western part of the state. The population was 5,787 in 1950 and 5,015 in 1940 by the federal census. It is served by the Northern Pacific and the Minneapolis, St. Paul and Soo Ste. Marie railways, and is the junction of federal highways 10 and 59. It has a mayor-council form of government. The electric, water and sewerage utilities are municipally owned. The surrounding area is good agricultural country, studded with many lakes, one of the largest being Detroit lake. These attract a large summer tourist and winter-sports trade.

A short distance to the north is the White Earth Indian reservation.

DETTINGEN, a village of Germany (Bavaria), 10 mi. NW of Aschaffenburg, scene of the battle of Dettingen (1743) (see AUSTRIAN SUCCESSION WAR OF 1740).

DE TUCIC, SERGE (1873-1940), Croatian playwright, was born in Požega, Croatia, later Yugoslavia.

After working as a sculptor for a short time he began to write for the theatre. His play *Truly Dum* (1896) was translated into several languages and was widely produced in southern Europe.

In 1904 King Ferdinand of Bulgaria made him the first director of the National theatre in Sofia. During World War I he went to London, where in 1914 he published a book on the Slav nations and later wrote a play, *The Liberator*, produced under the sponsorship of George Bernard Shaw and H. Wickham Stead.

He was for two years professor of Slavonic languages in King's college, London.

In 1918 he went to the United States. He died in New York city, Sept. 25, 1940.

DEUCALION, in Greek legend, son of Prometheus, king of Phthia in Thessaly, husband of Pyrrha and father of Hellen,

the mythical ancestor of the Hellenic race. When Zeus had resolved to destroy all mankind by a flood, Deucalion constructed a boat in which he landed on Mt. Parnassus with his wife.

Having offered sacrifice and inquired how to renew the human race they were ordered to cast behind them the "bones of the great mother", that is, the stones from the hillsides. Those thrown by Deucalion became men, those thrown by Pyrrha, women.

DEUCE, a term applied to the "two" of any suit of cards, or of dice. It is also a term in tennis when both sides have each scored three points in a game, or five games in a set, to win the game or set, two points or games must then be won consecutively, and the players return to a position of equality as often as they cannot score two such points or games consecutively. The earliest instances in English of the use of the slang expression "the deuce" in exclamations date from the 17th century.

DEUS, JOÃO DE (1830-1896), the greatest Portuguese poet of his generation, was born at Messines in Algarve on March 8, 1830. Matriculating in the faculty of law at the University of Coimbra, he settled in the city, dedicating himself wholly to the composition of verses, which circulated among professors and undergraduates in manuscript copies.

In the volume of his art, as in the conduct of his life, he practised a rigorous self control. He printed nothing previous to 1855, and the first of his poems to appear in a separate form was *La Lata* in 1860.

In 1862 he left Coimbra for Beja, where he was appointed editor of *O Bejense*, and four years later he edited the *Folha do Sul*. As the pungent satirical verses entitled *Elações* prove, he was not an ardent politician and, although he was returned as Liberal deputy for the constituency of Silves in 1868, he acted independently and promptly resigned his mandate. The renunciation implied in the act, which cut him off from all advancement, is in accord with nearly all that is known of his lofty character.

In 1868 his friend Jose Antonio Garcia Blanco collected from local journals the series of poems *Flores do campo*, which is supplemented by the *Ramo de flores* (1875). This is João de Deus's masterpiece.

The *Folhas soltas* (1876) is a collection of verse in the manner of *Flores do campo*, brilliantly effective and exquisitely refined. Within the next few years the writer turned his attention to educational problems. This was a misfortune for Portuguese literature, his educational mission absorbed João de Deus completely and is responsible for many publications which were of no literary value. A copy of verses in Antonio Vieira's *Graúda de Maria* (1877), the *Loas á Virgem* (1878) and the *Proverbios de Salomão* are evidence of a complete return to orthodoxy during the poet's last years.

He died at Lisbon, Port., on Jan. 11, 1896, and was accorded a public funeral in the National Pantheon at Belem.

Next to Luis de Camoens and perhaps João Garrett, no Portuguese poet was more widely read, more profoundly admired than João de Deus, yet no poet in any country was more indifferent to public opinion and more deliberately careless of personal fame. He is not responsible for any single edition of his poems, which were put together by ill-informed enthusiasts who ascribed to him verses that he had not written, he kept no copies of his compositions, seldom troubled to write them himself and was content for the most part to dictate them to others. And yet, though he never appeared to the patriotic spirit, though he wrote nothing at all comparable in force or majesty to the restrained splendour of *Os Lusadas*, the popular instinct which linked his name with that of his great predecessor, Camoens, was just. For Camoens was his model, not Camoens of the epic, but the Camoens of the lyrics and the sonnets, where the passion of tenderness finds its supreme utterance. Theophilus Braga, who published Deus's scattered minor prose writings and correspondence, noted five stages of development in his artistic life—the imitative, the idyllic, the lyric, the pessimistic and the devout phases.

But it is as the singer of love that João de Deus delights posterity as he delighted his own generation. The elegiac music of *Rachel* and of *Maria*, the melancholy of *Adieu* and of *Remorso*,

- 1 Air view showing the Detroit river and Belle Isle in the distance, Canada is at the right.
- 2 Campus Martius (right foreground) and Woodward avenue Detroit's principal street

VIEWS OF DETROIT

the tenderness and sincerity of *Meu casto luto*, of *Lagrima celeste*, of *Descalga* and 1 score more songs are distinguished by the large, vital simplicity which withstands time. It is precisely in the quality of unstudied simplicity that Joao de Deus is incomparably strong. The temptations to a display of virtuosity are almost irresistible for a Portuguese poet, he has the tradition of virtuosity in his blood, he has before him the example of all contemporaries, and he has at hand an instrument of wonderful sonorousity and compass. Yet not once is Joao de Deus clamorous or rhetorical, not once does he indulge in idle ornament. His prevailing note is that of exquisite sweetness and of reverent purity, yet with all his caressing softness he is never sentimental, and though he has not the strength for a long fight, emotion has seldom been set to more delicate music.

Had he included among his other gifts the gift of selection, had he continued the poetic discipline of his youth instead of dedicating his powers to a task which well as he performed it, might have been done no less well by a much lesser man, there is scarcely any height to which he might not have risen.

DEUSEDIT, or ADEODATUS, pope and saint (7-618), became pope on Oct. 19, 615, and died on Nov. 3, 618. The few decretals ascribed to him are unauthenticated and nothing is really known about him.

He is said to have been the first pope to use leaden seals for pontifical documents. From these seals came the word bull (*bullo*, a "leaden seal").

DEUSSEN, PAUL (1845-1919), German philosopher and Sanskrit scholar, was born at Oberdreis on Jan. 7, 1845. He taught at Berlin (1881-89), and then became professor of philosophy in Kiel where he died on July 7, 1919. As a philosopher, Deussen regarded the spatial world and objects as forms of the all important empirical consciousness. The reality for him lay in a nonspatial, nontemporal and noncausal sphere to which we attain by moral activity rather than by intellect.

DEUTERIUM AND TRITIUM Deuterium and tritium are the isotopes of hydrogen of atomic weights 2 and 3 respectively. The former is a stable atomic species found in natural hydrogen compounds (water being the most abundant) to the extent of 0.014% to 0.015%. The latter is a radioactive species emitting negative beta particles of 19,000 electron volts energy and having a half life of 12.5 years; it occurs in natural water (Norwegian snow) with an abundance of 10^{-18} of that of natural hydrogen. The names, symbols and some atomic constants of the three hydrogen isotopes and the neutron are given in Table I.

TABLE I—Atomic Constants of Neutron and Hydrogens

Name	Symbol	Atomic weight (physical scale)	Nuclear spin	Nuclear magnetic moment*
Neutron	n	1.008665	$\frac{1}{2}$	-1.9135
Protium	H or ^1H	1.007825	$\frac{1}{2}$	$+2.7928$
Deuterium	D or ^2H	2.014102	1	$+0.8576$
Tritium	T or ^3H	3.016049	$\frac{3}{2}$	$+2.9795$

*In units of nuclear Bohr magnetons ($= \frac{eh}{4\pi mc}$)

Deuterium was discovered (1931) by H. C. Urey with the help of F. G. Brickwedde and G. M. Murphy. Urey, using the third law of thermodynamics and the Debye theory of the solid state, predicted a difference in vapour pressures of H_2 and HD and thus the possibility of separating these substances by distillation of liquid hydrogen. The deuterium was detected in the residue of a distillation of liquid hydrogen by its atomic spectrum. L. W. Alvarez and R. Cornog (1939) discovered tritium by bombarding deuterium with high energy deuterons,

W. F. Libby and A. V. Grosse showed that it is present in natural water. Neutrons produced by the action of cosmic rays probably produce this tritium by reacting with nitrogen in the high atmosphere,

Deuterium was first prepared in pure form by G. N. Lewis using

the electrolytic method of concentration discovered by E. W. Washburn. When a water solution of an electrolyte (NaOH usually) is electrolyzed, the hydrogen produced contains a smaller fraction of deuterium than the water and hence deuterium is concentrated in the residue. Very nearly pure deuterium oxide (heavy water) is secured when the residue is reduced to $\frac{1}{100,000}$ of the original water. This method of preparation was used before World War II for the commercial preparation of D₂O and later in Norway for the large scale preparation. During the war other methods for the preparation of D₂O were devised and subsequently used to produce large quantities of this substance. These methods depend upon the substantial differences in chemical and physical properties of the compounds of protium and deuterium. F. G. Brickwedde used the distillation of liquid hydrogen to produce hydrogen deuteride (HD) and studied its properties (see below).

Tritium is produced most effectively by the nuclear reaction between Li^7 and neutrons from nuclear fission reactors, i.e.,

The compounds of the three hydrogen isotopes differ quantitatively in their physical properties though they are very similar to each other qualitatively. This is shown by the physical properties of the waters (see Table II) and of the elementary substances (see Table III). The same is true of their chemical properties as is illustrated by the exchange reactions,

If the protium and deuterium or tritium compounds had exactly the same chemical properties, the equilibrium constant for each reaction would be unity. Since both constants are greater than unity the ratios of the isotopes D/H and T/H are less in the hydrogen gases than in the corresponding waters when equilibrium is established. Similar differences are characteristic of other exchange reactions of this type. Such differences in properties are potentially useful for devising separation processes for protium and deuterium.

The velocities of reactions of the compounds containing deuterium or tritium are usually less than those in which protium is present and these differences are often large. Protium reacts 13.4 times as rapidly with chlorine at 0°C than does deuterium.

The nucleus of the deuterium atom, the deuteron, proved to be especially useful in understanding the structure of atomic nuclei. It consists of one proton and one neutron and hence is the nuclear two body problem just as the hydrogen atom consisting of one nucleus and one electron is the two body problem of atomic structure.

TABLE II—Physical Properties of the Waters

	D ₂ O	H ₂ O
Specific gravity d_{20}^{20}	1.10715	1.00000
Melting point ($^\circ \text{C}$)	1.81	0
Boiling point ($^\circ \text{C}$)	101.41	100
Temperature of maximum density ($^\circ \text{C}$)	11.3	3.98
Critical temperature ($^\circ \text{C}$)	373.5	374.2
Critical pressure (atm)	218.6	218.2
Critical density (g/ml)	0.363	0.325

TABLE III—Physical Properties of the Elementary Substances

	H ₂	DH	D ₂	T ₂
Gram molecular volume of the solid (cc) at the triple point ($^\circ \text{K}$)	21.5	21.82	20.45	—
Triple point ($^\circ \text{K}$)	13.81	18.60	18.71	20.6
Vapour pressure at triple point (mm)	54.0	92.8	128.0	162.0
Boiling point ($^\circ \text{K}$)	20.39	23.13	21.97	23.01
Heat of fusion at triple point	28.0	38.1	37.0	—
Heat of vapourisation (cal/mol at temperature shown)	216 (20.39°K)	257 (23.13°K)	205 (21.97°K)	333 (23.01°K)

and theory. Because of the comparative simplicity of the theoretical problem it has been possible to compare theoretical calculations effectively with observational data. The theory shows that the attractive forces between the neutron and proton are very short range in character and cannot follow any inverse square law. They appear to be the meson forces introduced by H. Yu-

law. The normal state of the deuteron is ^2Si , with a binding energy of 186000 electron volts. This is the only stable state. The triton consists of two neutrons and one proton and already presents a three-body problem of much greater complexity, but still of great usefulness in these problems.

The biological effects of deuterium oxide are of considerable interest. It has been established that neither plants nor animals continue to live and thrive in water containing deuterium oxide of high concentrations. At mid 20th century, no case of acclimation to the deuterium oxide was known.

Both deuterium and tritium are very useful as isotopic tracers in the investigation of chemical and biochemical reactions. The rather marked differences in chemical properties are sometimes troublesome (more so in the case of tritium than in that of deuterium). Deuterium particularly has been used in this way since it is readily available and easy to analyze. These tracers made possible a much greater understanding of biochemical processes. In general the heavier isotopes of hydrogen have proved to be of interest in so many aspects of the chemistry of hydrogen that no general review is possible since an adequate review would cover the entire chemistry of the element.

Deuterium oxide is useful in atomic energy engineering problems as a moderator in reactors. It has the advantage of being a liquid which absorbs neutrons only slightly, with an absorption cross section of only $0.0002 \times 10^{-24} \text{ cm}^2$ for D-O as compared with $0.6 \times 10^{-24} \text{ cm}^2$ for H-O. At mid-century it was expected to be of great industrial use.

Because of their low atomic numbers, i.e., charges on their nuclei, deuterium and tritium are of interest in connection with thermonuclear reactions. The mass change in reaction (1) is 0.0033 g , and using the relativity relation between mass and energy, namely, $E=mc^2$, this gives 4.5×10^{10} calories per gram atom of deuterium. Thus about 0.1% of the mass is converted to heat energy. Tritium is likewise capable of liberating large quantities of energy but must be produced by costly processes, while deuterium is relatively inexpensive. At mid century, controlled thermonuclear reactions suitable for sources of power seemed unlikely to be devised in the near future.

DEUTERONOMY, the fifth book of the Law in the Old Testament. The name is a Greek mistranslation of the term *Mishneh haTorah*, "copy of the Law," found in Deut. xvi, 18, and Josh. viii, 32. It is ostensibly an account of the Law as given by Moses just before his death in the plains of Moab, the theory of the book being, apparently that the Law given 38 years earlier at Horeb was confirmed to the "Ten Words" (see **DECALOGUE**), and that the present precepts are offered as a rule for life in the country which Israel will soon enter.

Contents and Structure—The book falls into the following well-marked divisions: (1) i, i-iv, 43 Introductory discourse by Moses, mainly a historical retrospect (2) iv, 44-xi, 32 A second introduction, consisting of a repetition of the Decalogue and an exhortation to observe the Law (3) xi-xxviii A code containing both religious and civil laws and including in ch. xxvii instructions for the solemn ratification of the Law after the conquest of Canaan. (4) xxix-xxxii Concluding exhortation, with Moses' farewell to Israel (5) xxxiii and xxxiv Two poems ascribed to Moses, the latter being a collection of tribal songs similar in form to Gen. xlii (6) xxxv The death of Moses.

The original extent of the book is not fully determined. It may well have begun with iv, 44, or even with xi, 1 (though this is

less probable). Ch. xxviii, xxix-xxxiv may have been later appendices and it is extremely unlikely that the two poems formed a part of the original book. There are signs of a double tradition e.g., xi, 2-7 and 8-14, cover the same ground ostensibly. The curious variation between the use of the second plural and the second singular in addressing Israel has led some scholars to believe that we have here the interweaving of two different documents, though it must be admitted that the two forms interchange so frequently and irregularly that analysis on this basis is most precarious. The tone and style of the book are very clearly marked. The whole has a humanitarian outlook, which is manifested both in modifications of existing laws and in the promulgation of new regulations. It thus contains repeated exhortations to love Yahweh and to recognize His love to Israel. The ritual and ceremonial elements are comparatively slight.

Date—1 *Comparative* There are three other codes with which Deuteronomy may be compared and the relation of the book to the work of some of the prophets, especially Hosea and Ezekiel, is of importance. In its present form it seems to be later than the Book of the Covenant (Exod. xx-xxiii) and Hosea and earlier than the Priestly Code and, probably, Ezekiel. It may also be a little earlier than the Law of Holiness, though the affinities between these two documents suggest some connection. The order JE, D, Ezekiel, P, is, however, generally accepted.

2 *Absolute* Part of the importance of Deuteronomy for the history of Hebrew literature and thought lies in the fact that it seems possible to assign an actual date to its promulgation. Its main ritual provision, the concentration of sacrifice, finds practical expression in the religious measures of Josiah, 621 B.C. (II Kings xxi, xxiii) and Deuteronomy, or a nucleus of the book has therefore been identified with the Book of the Law found by Hilkiah in the temple. If that view be correct, then Deuteronomy is a "program" based on the teaching of the 8th century prophets and compiled during the 7th century.

While this is the "regnant hypothesis," it has not passed unchallenged. It involves two difficulties. One is that the provisions—or some of them—intended to meet the new order are unworkable in practice. Even in II Kings xxi, 9, it is stated that the priests of the local sanctuaries, brought to Jerusalem as prescribed in Deut. xxi, 6-8, were not permitted to share in the offices performed by the Jerusalem priesthood in the temple. The other difficulty is that while the reform of Josiah tended to exalt Jerusalem, the Book of the Covenant (on which the Deuteronomistic code is clearly based) and the historical traditions followed in Deuteronomy are of northern provenance, belonging to E rather than to J. Attempts have been made to solve these problems by throwing the date of the book either forward or backward. Here it can only be remarked that these solutions raise other difficulties which would also have to be solved.

Whatever the exact date of the book may have been, its influence on Hebrew literature and thought is undeniable. In its spirit and from its point of view the Book of Kings was written, and some of the material now found in our prophetic books (especially Jeremiah) bears the same stamp, alike in matter and in style. It sprang out of and represents one of the most important schools of thought in the history of Israel.

DEUTSCH, IMMANUEL OSCAR MENAHEM (1829-1873), German orientalist, was born of Jewish extraction at Neisse on Oct. 28, 1829. His studies at the University of Berlin made him an excellent Hebrew and classical scholar, and in 1855 he became assistant in the British Museum library.

Deutsch worked intensely on the Talmud and contributed more than 190 papers to *Chambers's Encyclopaedia*. His famous article on the Talmud in the *Quarterly Review* for Oct. 1867 was translated into many European languages. He died at Alexandria on May 12, 1873. His *Literary Remains* were edited by Lady Strangford in 1874.

DEUTSCHE BANK, established in 1870, became Germany's

largest commercial bank as a result of numerous mergers. The absorption of banks in western Germany strengthened its position in the highly industrialized Ruhr area. The merger with the Disconto Gesellschaft in 1929 united Germany's two largest banks. The combined institution was called the Deutsche Bank. The assets of the bank increased from 3,700,000,000 RM in 1938 to 8,700,000,000 RM in 1943. About 85% of this increase consisted of government securities, which accounted for 59% of total assets in 1943. The capital of the bank was raised from 130,000,000 RM to 160,000,000 RM in 1930 because of the rising volume of deposits and the increase in participations in foreign banks.

The head office of the bank was in Berlin. In 1941 the bank had 489 branches and agencies. Particularly before and during World War II it developed an extensive foreign system, with branches in many countries including Turkey, Czechoslovakia and Poland, in addition, it obtained controlling interests in foreign banks. Its subsidiary, the Deutsche Überseebank, was the largest and most influential German bank for South America; in 1938 it had 21 branches, mainly in Argentina, Brazil, Chile, Peru, Uruguay and Spain.

The bank had close relations with numerous industrial enterprises. Important firms, such as Siemens and Halske A. G., I. G. Farbenindustrie A. G. and Mannesmannröhren Werke A. G. were represented on its board of directors. The head office of the bank in Berlin was closed in 1945, and its branches in eastern Germany were liquidated. (H. A. A.)

DEUTSCHER LANDER, BANK, is the central note issuing bank of western Germany. It was established in 1948 in Frankfurt as part of the Allied decentralization of the German banking system replacing the Reichsbank. (q.v.)

The bank is the "bank of the Land central banks." Its board of directors consists of a chairman, the president of the board of managers and the presidents of the Land central banks. The bank is not allowed to maintain branches or subsidiaries, but the Land central banks, with their numerous branches, perform the functions of subsidiaries. The bank is not subject to instructions of any political body or public nonjudicial agency.

The bank's transactions with central banks include purchase and sale of foreign exchange and valuable metals, acceptance of deposits, rediscount bills of exchange, and advances against bills of exchange, treasury bills or other securities of the federal government and the *Land*. It may grant the federal government short-term advances in anticipation of specific revenues, generally not to exceed 1,500,000,000 DM. It may act as fiscal agent for the federal government and buy and sell its treasury bills and fixed interest-bearing securities in the open market.

The bank controls credit through its power to issue directives to the Land central banks, reject bills bought for rediscount, change requirements for both minimum reserves the Land central banks must keep with it and those which commercial banks must keep with Land central banks, and alter the discount rate.

The bank had assets of 13,600,000,000 DM in 1950. Its capital of 100,000,000 DM was subscribed by the Land central banks in proportion to their deposits, annual profits, after establishment of reserves, are distributed to these banks in proportion to their capital participation. (H. A. A.)

DEUTSCHKRONE, a town formerly in the east of the *Land* of Prussia, Ger., between the two lakes of Arens and Radau, 15 mi N W of Schneidemühl, a railway junction 60 mi N of Poznan. Pop. (1946) 7,816.

DLUTZ

It
The fortifications were finally razed in 1888

DEUX-SEVRES, an inland department of western France, formed in 1790 mainly of the three districts of Poitou: Thouars, Gâtine and Niortais, added to a small portion of Sautonne and a still smaller portion of Aunis. Area, 2,338 sq mi. Pop. (1946) 312,756. It is bounded N by Maine et Loire, E by Vienne, S E by Charente, S by Charente Maritime and W by Vendée. The Sevre of Niort traverses the southern portion, and the Sevre of Nantes (an affluent of the Loire) drains the northwest. There are three regions—the Gâtine, in the north and centre, the Plaine in the south and the Marais—distinguished by their geological and physical character. The Gâtine, formed of primitive rocks (granite and schists) is the continuation of the "Boisge" of Vendée and Maine et Loire. Its surface is irregular and covered with hedges and clumps of wood or forests. Application of lime has improved the soil, which is naturally poor. The Plaine, resting on oolite limestone, is treeless but fertile. The Marais, a low lying alluvial district in the extreme southwest, is extremely productive, when properly drained. The highest points, several above 700 ft., are found in a line of hills which begins in the centre of the department, to the south of Pailhauy and stretches north west into the neighbouring department of Vendée. It divides the region drained by the Sevre Niortaise and the Thouet (both affluents of the Loire) in the north from the basins of the Sevre Niortaise and the Charente in the south.

The climate is mild; the annual temperature at Niort being 52°, the rainfall nearly 25 in. Winters are colder in the Gâtine, summers warmer in the Plaine.

Three quarters of the entire area of Deux-Sevres, which is primarily an agricultural department, consists of arable land. Wheat and oats are the main cereals. Potatoes and mangel wurzels are the chief root crops. Niort is a centre for the growing of vegetables (onions, asparagus, artichokes, etc.) and of angelica. Much beetroot is raised to supply the distilleries of Melle. Colza, hemp, rape and flax are also grown. Vineyards are numerous in the neighbourhood of Bressuire in the north, and of Niort and Melle in the south. The department is well known for the Parthenay breed of cattle and the Poitou breed of horses, and good mules are reared in the south. The system of co-operative dairying is practised in some localities.

The apple trees of the Gâtine and the walnut trees of the Plaine bring a good return.

Some coal is mined, and the department produces building stone and lime.

There is manufacture of textiles (serges, druggets, linen, handkerchiefs, flannels, and knitted goods). Tanning and leather dressing are carried on at Niort and other places, and gloves are made at Niort.

Wool and cotton spinning, hat and shoe making, distilling, flour milling and oil refining are also main industries. The department exports cattle and sheep to Paris and Poitiers, also cereals, oils, wines, vegetables and its industrial products.

The Sevre Niortaise and its tributary the Mignon furnish 19 mi of navigable waterway. The department is served by the Ouest-Etat railway. It contains a large proportion of Protestants, especially in the southeast. The three *arrondissements* are Bressuire, Niort and Parthenay, the cantons number 31, and the communes 357.

Deux-Sevres is part of the region of the IXth Army Corps (Tours) and of the diocese and the *académie* (educational jurisdiction) of Poitiers, where also is its court of appeal.

Niort (the capital), Bressuire, Melle, Parthenay, St. Maixent, Thouars and Oiron are the principal places in the department. Several other towns contain features of interest. Among these are Airvault, where there is a church of the 12th and 14th centuries which once belonged to the abbey of St. Pierre, and an ancient bridge built by the monks, Celles-sur-Belle, where there is an old church rebuilt by Louis XI, and again in the 17th century, and St. Joun de-Marnes, with a fine Romanesque abbey church with Gothic restoration.

DEVA, a Roman legionary fortress in Britain on the Dee at the site of the modern Chester (q.v.)

DEVA, DEWA, in the Zoroastrian mythology the Dew

as a fuel for gas turbines in the generation of electricity and for a lobster storage and marketing scheme.

Fisheries have been aided by grants for research with the assistance of a scientific advisory committee, to the fisheries departments and independent institutions with the object of studying the resources of seas, rivers and lakes. Fishery harbours have been improved, particularly in Scotland.

DEVENS, CHARLES (1820-1891), U.S. lawyer and jurist, was born in Charlestown, Mass., April 4, 1820. He graduated at Harvard college in 1838, and at the Harvard law school in 1840, and was admitted to the bar. Throughout the Civil War he served in the Federal army, becoming colonel of volunteers in July 1861 and brigadier general of volunteers in April 1862. After the war he was a judge of the Massachusetts superior court from 1867 to 1873, and was an associate justice of the supreme court of the state from 1873 to 1877, and again from 1881 to 1891. From 1877 to 1881 he was attorney general of the United States in the cabinet of Pres. Rutherford B. Hayes. He died at Boston, Mass., on Jan. 7, 1891.

See his *Orations and Addresses*, with a memoir by John Codman Ropes (Boston, 1891).

DEVENTER, SIR JACOB LOUIS VAN (1874-1922), South African soldier was born in the Orange Free State. He fought in the South African War of 1899-1902, becoming second in command to Gen. Jan Christiaan Smuts during the latter's invasion of Cape Colony. A colonel on the permanent staff of the South African defense force, Van Deventer served with distinction in German South West Africa, 1914-15. His gifts were shown later in the operations in East Africa, where in May 1917 he was appointed commander in chief in succession to Smuts. He was then a major general, and was given the temporary rank of lieutenant general on becoming commander in chief. Shortly after war, he was appointed K.C.B. As commander in chief he brought the campaign to a successful end. He died on Aug. 27, 1922. (See EAST AFRICA OPERATIONS in.)

DEVENTER, A, a town in the province of Overysel, the Netherlands on the right bank of the Ysel, at the union of the Schipbeek, and a junction station 10 mi. N. of Zutphen. Pop. (1947) 44,089. In the 14th century Deventer was the centre of the famous religious educational movement associated with the name of Gerhard Groot (qv), who was a native of the town (see BROTHERS or COMMON LIFE). The Groote Kerk (St. Lebuinus) dates from 1334 and occupies the site of an older structure of which the 11th-century crypt remains.

The Roman Catholic Broederkerk, or Brothers' church, contains among its relics three ancient gospels attributed to St. Lebuinus (Lebwin), the apostle of the Frisians and Westphalians (d. c. 773). The Bergkerk, dedicated in 1206, has two late Romanesque towers. The town hall was built in 1693. In the fine square called the Brink is the old weigh house, now a school (*Gymnasium*), built in 1528, with a large external staircase (1644). The town library, also called the library of the Athenaeum, includes many manuscripts and incunabula, and a 13th-century copy of *Reynard the Fox*. The archives of the town are of considerable value. Besides a considerable agricultural trade, Deventer has important carpet and textile factories (the Smyrna carpets being especially famous).

In the church of Bathmen, a village 5 mi. E. of Deventer, some 14th century frescoes were discovered. German troops occupied Deventer in 1940.

DE VERE, AUBREY THOMAS (1814-1902) Irish poet and critic, was born at Curragh Chase, County Limerick, being the third son of Sir Aubrey de Vere Hunt (1788-1846), also a poet, whose verses and a drama, *Mary Tudor*, were published by his son in 1875 and 1884. Aubrey de Vere was educated at Trinity college, Dublin, and in his 28th year published *The Waldenses*, the first of his many volumes of verse and prose. In many of his poems, notably in the volume of sonnets called *St. Peter's Chans* (1888), he made rich additions to devotional verse. After Matthew Arnold's fine lecture on "Celtic Literature," nothing perhaps did more to help the Celtic revival than Aubrey de Vere's insight into the Irish character and his reproductions of the early Irish

epic poetry.

See *Selections* ed. by G. E. Woodberry (New York, London, 1891), Geoffrey Taylor (ed.), *Irish Poets of the Nineteenth Century* (London, 1951).

DEVIATION, in magnetism (qv), the horizontal angle through which a magnetic needle is deflected away from the magnetic meridian by the iron in a ship (see COMPASS).

DEVICE, a scheme or simple mechanical contrivance, also a design, particularly a heraldic design or emblem, often combined with a motto or legend. (See HERALDRY.)

DEVADASI (DEVADASI) see CASTE (INDIAN).

DEVIL is the generic name for a spirit of evil especially the supreme spirit of evil, the foe of God and man, but also for minor evil spirits or demons. It is given as a name to many destructive and repulsive animals, to apparatus for tearing cloth, etc. to highly seasoned dishes to boy assistants in printing houses (probably because of their inky appearance) and to juniors and hacks who prepare work (or "devil") for barnstormers, authors, etc. Here, however, we are concerned with the word only as used in mythology and religion.

The primitive philosophy of animism involves the ascription of all phenomena to personal agencies, the agents of good become gods, those of evil, demons. When the divine is most completely conceived as unity, the demonic is also so conceived, and over against God stands Satan or the devil.

Though it is in connection with Hebrew and Christian monotheism that belief in the devil has been most fully developed, there are approaches to the doctrine in other religions, e.g., "the lady Nina" and the dragon Tiamat in Babylonian, the serpent Apap in Egyptian, the Titans and Prometheus in Greek, Hel and Loki among the Teutons and Ahu and Siva among Hindus. The opposition of good and evil is most fully carried out in Zoroastrianism. Opposed to Ormuzd, the author of all good is Ahriman, the source of all evil, and the opposition runs through the whole universe (D'Alviella's *Hubert Lectures*, pp. 158-164).

The conception of Satan belongs to the postbiblical period of Hebrew development, and probably shows traces of the influence of Persian on Jewish thought, it also has its roots in much older beliefs (cf. 1 Sam. xvi, 14, Judges ix, 23, 1 Kings xxi, 22, Gen. vi, 1-4), and evil, whether as misfortune or as sin, is generally assigned to divine causality (1 Sam. xviii, 10, 2 Sam. xxiv, 1, 1 Kings xxi, 20, Isa. vi, 10, lxx, 17). After the exile there is a tendency to protect the divine transcendence by the introduction of mediating angelic agency, and to separate all evil from God by ascribing its origin to Satan, the enemy of God and man. In the prophecy of Zechariah (iii, 1, 2) he stands as the adversary of Joshua, the high priest, in the book of Job he presents himself before the Lord among the sons of God (ii, 1), yet is represented both as accuser and tempter, and while, according to 2 Sam. xxiv, 1, God himself tests David in regard to the numbering of the people, according to 1 Chron. xxi, 1, it is Satan who tempts him.

The development of the conception continued in later Judaism, which was probably more strongly influenced by Persian dualism, as in Tobit iii, 8, vi, 14, Ecclesiasticus xvi, 27, Wisdom ii, 24, Psalms of Solomon xvii, 49, and the book of Enoch. In the Jewish *Targum* Sammael "the highest angel that stands before God's throne, caused the serpent to seduce the woman", he coalesces with Satan, and has inferior Satans as his servants. The birth of Cain is ascribed to a union of Satan with Eve. As accuser affecting man's standing before God he is greatly feared.

This doctrine, stripped of much of its grossness, is reproduced in the New Testament. Satan is the *διάβολος*, from *διαβάλλειν*, to slander (Matt. xiii, 39, John xiii, 2, Eph. iv, 27, Heb. ii, 14, Rev. ii, 10), slanderer or accuser, the *πειράζων* (Matt. iv, 3, 1 Thess. ii, 5), the tempter, the *σαρμὰς* (Matt. v, 37, John xvii, 15, Eph. vi, 16), the evil one, and the *ἐχθρός* (Matt. xiii, 39), the enemy. He is apparently identified with Beelzebub (or Beelzebul) in Matt. xii, 26, 27. Jesus appears to recognize the existence of demons belonging to a kingdom of evil under the leadership of Satan "the prince of demons" (Matt. xii, 24, 26, 27), whose works in demonic possessions it is his function to destroy (Mark

1 34 11 11 11 7 Luke x 17-20) but he himself conquers Satan in resisting his temptations (Matt iv 1-11). Simon is warned against him, and Judas yields to him as tempter (Luke xxi 31, John xiii 7). Jesus's crucifixion is represented as a triumph over Satan (Luke x 18). This Jewish doctrine is found in Paul's letters also. Satan rules over a world of evil. Paul's own "strike in the flesh" is Satan's messenger (2 Cor xii 7). According to Hebrews Satan's power over death Jesus destroys by dying (in 14). Revelation describes the war in heaven between God with his angels and Satan or the dragon, the "old serpent," the discover of the whole world (xii 9), with his hosts of darkness under the authority of the Beast and the kings of the earth, Satan is imprisoned in the bottomless pit a thousand years (xv 2). As an angel to deceive the nations, he is finally cast into the lake of fire and brimstone (xv 2). Cf. Enoch iv 5, 6, 2 Peter i 4). In John's Gospel and Epistles Satan is opposed to Christ. Sinners and murderers from the beginning (i John ii 8) and live by nature. (John viii 44). He enslaves men to sin (viii 34), causes death (verse 44), rules the present world (xiv 30), but has no power over Christ or those who are His (xiv 30, xvi 11, i John v 18). He will be destroyed by Christ with all his works (John xvi 33, i John ii 8).

In the common faith of the Gentile Churches after the Apostolic age the influence of polytheism survived in the belief in the dominion of demons from which Christ is the Redeemer. While Christ's First Advent delivered believers from Satan's bondage, his overthrow would be completed only by the Second Advent. The belief in Satan appears in fantastic forms in Gnosticism. The Gnostics traced false doctrine as well as evil practice to him. In Irenaeus emerges the strange doctrine that the death of Christ was a ransom paid to the devil. God was represented by Origen as duping the devil, and His right to do so was justified. While this view was maintained by several Christian thinkers, others felt scruples about ascribing a "pious fraud" to God, and it at last fell into the background. The possibility of the redemption of Satan, advanced by Origen however, was in the 5th century branded as a heresy. Persian dualism was brought into contact with Christian thought in the doctrine of Mani, and it is permissible to believe that the gloomy views of Augustine regarding man's condition are due in some measure to this influence. Man taught that Satan attacked the earth, and defeated man sent against him by the God of light, but was overthrown by the God of light, who then delivered the primal man. "During the middle ages," says Tulloch, "the belief in the devil was absorbing—suns conceived themselves and others to be in constant conflict with him." This superstition perhaps at its strongest in the 13th to the 15th century, passed into Protestantism. Luther was always conscious of the presence and opposition of Satan. He held that this world will pass away with its pleasures, as there can be no real improvement in it for the devil continues in it to ply his daring and seductive devices. This belief in the devil was especially strong in Scotland among both clergy and laity in the 17th century.

In more recent times a great variety of opinions has been expressed on this subject. The reality of demonic possession has been denied and Satan variously represented as a personification of the principle of evil. But some Christian theologians, such as Daul, Dornier, Martensen have tried to form a speculative defence of the common belief. A Ritschli gives no place in his constructive doctrine to the belief in the devil, but recognizes that the mutual action of individual sinners on one another constitutes a kingdom of sin opposed to the kingdom of God (A. E. Garvie, *The Ritschlian Theology*, p. 304). In the book entitled *Evil and Exaltation* there is 'an attempt to turn the light of modern science on to the ancient mystery of evil.' The author contends that the existence of evil is best explained by assuming that God is confronted with Satan, who in the process of evolution interferes with the divine designs, an interference which the instability of such an evolving process makes not incredible. Satan is however held to be a creature who has by abuse of his freedom been estranged from, and opposed to his Creator, and who at last will be conquered by moral means. W. M. Alexander in his book on demonic possession maintains that "the confession

of Jesus as the Messiah or Son of God is the classical criterion of genuine demonic possession" (p. 150) and argues that as "the Incarnation indicated the establishment of the kingdom of heaven upon earth," there took place "a counter movement among the powers of darkness," of which "genuine demonic possession was one of the manifestations" (p. 249).

Interesting as these speculations are, it may be confidently affirmed that belief in Satan is not now generally regarded as an essential article of the Christian faith, nor is it found to be an indispensable element of Christian experience. On the one hand science has so explained many of the processes of outer nature and of the inner life of man as to leave no room for Satanic agency. On the other hand the modern view of the inspiration of the Scriptures does not necessitate the acceptance of the doctrine of the Scriptures on this subject as finally and absolutely authoritative. The preaching of Jesus even in this matter may be accounted for as either an accommodation to the views of those with whom He was dealing, or more probably as a proof of the limitation of knowledge which was a necessary condition of the Incarnation, for it cannot be contended that as revealer of God and redeemer of men it was imperative that He should either correct or confirm men's beliefs in this respect. The possibility of the existence of evil spirits, organized under one leader Satan to tempt man and oppose God, cannot be denied, the sufficiency of the evidence for such evil agency may be doubted, the necessity of any such belief for Christian thought and life cannot, therefore, be affirmed. (See also DEMONOLOGY, POSSESSION.)

DE VILLIERS, JOHN HENRY, BARON (1842-1914), first Chief Justice of the Union of South Africa, was born at Pietermaritzburg, Cape Colony, in June 1842. He was educated at the South African college, Cape Town, and Utrecht and Berlin universities. In 1865 he was called to the bar by the Inner Temple and began practice in Cape Colony. Entering Cape politics in 1866, he was elected a member of the House of Assembly, became attorney general of the Colony in 1872 and two years later was appointed Chief Justice of the Cape. In this capacity he succeeded, by his decisions, in adapting the Roman-Dutch law of the colony to modern requirements. He was appointed President of the National Convention in 1908 and in 1910 was raised to the peerage on becoming Chief Justice of the Union of South Africa. He died Sept. 2, 1914.

DEVIL POSTPILE, a national monument (reservation) in the southeast corner of Madera county, California, U.S.A., and only a few miles southeast of Yosemite national park. The reservation (798.46 ac. in area) was created on July 6, 1911, to preserve an unusual mass of basaltic columns, 10 to 30 in in diameter, and rising like an immense pile of posts, as high as 60 ft. It is said to rank with the Giant's Causeway in Ireland.

DEVIL'S ADVOCATE see ADVOCATUS DIABOLI.

DEVIL'S ISLAND, a small island in the Atlantic Ocean off the coast of French Guiana, South America, formerly used by the French as a penal settlement because of the difficulty of escape. It was here that Capt. Alfred Dreyfus (*q.v.*) was confined.

BIBLIOGRAPHY—C. P. Bean, *Devil's Island* (London, 1939).

DEVILS LAKE, a city of North Dakota, U.S.A., on Devils Lake, 85 mi W by N of Grand Forks, the county seat of Ramsey county. It is on federal highway 2, and is served by the Great Northern and the Soo Line railways.

Population in the 1950 census was 6,419, in 1940 it was 6,204. The city has creameries, flour mills and railroad shops. It is the seat of the state school for the deaf. The state university has a biological station on the lake, and just south of the lake is Sully's Hill National park, an important wild animal preserve, with historic associations. Devils Lake was settled in 1880 and incorporated in 1887.

DEVILS TOWER, first of the U.S. national monuments, on the Belle Fourche river about 25 mi northwest of Sundance in Crook county, Wyoming, U.S.A. The area (1,193.97 ac.) was

established Sept. 24, 1906, to preserve a remarkable natural rock tower, of volcanic origin, 600 ft from base to summit and 1,300 ft above the Belle Fourche river.

DE VINNE, THEODORE LOW (1828-1914), the most eminent American printer during the latter 19th century and the first decade of the 20th. He was known as an authority on the history of typography and was the author of many scholarly books on this subject. Born at Stamford, Conn., on Dec. 25, 1828, he took the first steps toward learning his trade in 1843 in a printing office at Fishkill, N.Y., but entered on his regular apprenticeship soon after in the office of the *Gazette* at Newburgh, N.Y. In 1847 he went to New York city and after working in several offices, in 1849 entered the employ of Francis Hart, one of the leading printers in that city, a relation destined to prove both happy and permanent. From work as a job compositor, he graduated in 1850 into the position of foreman. Nine years later, when De Vinne was offered a partnership elsewhere, Hart decided to hold him by making him a member of the firm. At this period the business of Francis Hart and Co. was tending more and more to book printing, a field to which De Vinne devoted most of his efforts from that time onward. About 1864 De Vinne began to write on printing, his earliest contributions dealing with the economic aspects of the business, but his attention soon turned to the aspects of typographic style and the history of the craft.

In 1873 the firm began to print *St. Nicholas* and soon after took on the *Century Magazine*, in printing the illustrations for which some new standards were established. The *Century Dictionary* was another job of importance produced under De Vinne's direction.

Francis Hart died in 1877 and in 1883 the name of the firm was changed to Theodore L. De Vinne and Company, the plant coming to be known as the De Vinne press, which earned a reputation as the outstanding printing office of the country. De Vinne was one of the founders of the Grolier Club and one of its most active members, printing most of the early books issued by that organization, and writing or editing a number of them. He died on Feb. 16, 1914.

As a printer De Vinne was a craftsman of high standards and stood head and shoulders above his contemporaries, but he could not be regarded as a great creative artist. His simplest books were his best. De Vinne's most important contributions to typographic literature were *The Practice of Typography* (1900-04), a series of four manuals, *The Invention of Printing* (1876), *Christopher Plantin and the Plantin Moretus Museum at Antwerp* (1888), and *Notable Printers of Italy during the Fifteenth Century* (1910). (D. C. McM.)

DEVISE or DEVICÉ, the conveyance of real property by will. See **LEGACY**.

DEVIZES, a market town and municipal borough in the eastern parliamentary division of Wiltshire, England, 86 mi. S.W. of London by the G.W. Ry. Pop. (1933) 7,000. Area 2.2 sq. mi. Its castle was built on a tongue of land flanked by two deep ravines, behind which the town grew up on a stretch of exposed tableland. Its main streets, in which a few ancient timbered houses are left, radiate from the market place, where stands a market cross with a remarkable inscription referring to a certain dishonest market transaction in 1753. The Kennet and Avon canal, now practically disused, is raised to two levels of ten towers through a chain of locks. St. John's church (12th century), one of the most interesting in Wiltshire, is cruciform, with a massive central tower and fine Norman chancel, and contains several ancient monuments, besides some beautiful carved stonework and oak ceilings. St. Mary's, a smaller church, is partly Norman, but was rebuilt in the 15th and restored in the 19th century. Roundway Down, on the edge of which the town stands, stretches eastward and is the site of an ancient British earthwork, besides having yielded other remains. The county general and mental hospitals are situated in Devizes, which also has a museum, and is the depot of the Wiltshire regiment. It is an important corn, cattle and pig market, and has bacon and cheese factories, tleworks, engineering works and manufactures of snuff and tobacco. Assize courts are held at Devizes, which has its own commission of the

peace and court of quarter sessions.

The construction at Devizes in the reign of Henry I. of a castle of exceptional magnificence by Roger, bishop of Salisbury, at once constituted the town an important political centre, and the name itself is possibly a corruption of the mediaeval Latin referring to the "castle at the boundaries" (*ad devizas*). After the disgrace of Roger in 1139 the castle was seized by King Stephen. In the 14th century it formed part of the dowry of the queens of England. Devizes' first charter, from Matilda, confirmed by successive later sovereigns, merely grants exemption from certain tolls and the enjoyment of undisturbed peace. Edward III. added a clause conferring on the town the liberties of Marlborough, and Richard II. instituted a coroner. A gold merchant was granted by Edward I., Edward II. and Edward III., and in 1614 was divided into the three companies of drapers, mercers and leather-sellers. The present governing charters were issued by James I. and Charles I., the latter being little more than a confirmation of the former, which instituted the common council. Devizes returned two members to parliament from 1295 until deprived of one member in 1867, its representation was merged in that of the county in 1885.

See *Viet County Hist., Wiltshire, History of Devizes* (Devizes, 1899).

DEVOLUTION, WAR OF (1667-68), the name applied to the war which arose out of Louis XIV's claims to certain Spanish territories in right of his wife Maria Theresa, upon whom the ownership was alleged to have "devolved." (See, for the military operations, **DUTCH WARS**.) The war was ended by the Treaty of Aix-la-Chapelle in 1668.

DEVON, EARLS OF. From the family of De Redvers (De Ruparis, Rivers), who had been earls of Devon from about 1100, this title passed to Hugh de Courtenay (c. 1275-1349), but was subsequently forfeited by Thomas Courtenay (1432-1462), a Lancastrian who was beheaded after the battle of Towton. It was revived in 1485 in favour of Edward Courtenay (d. 1509), whose son Sir William (d. 1511) married Catherine, daughter of Edward IV. Too great proximity to the throne led to his attainer, but his son Henry (c. 1498-1539) was restored in 1517 as earl of Devon, and in 1525 was created marquis of Exeter, his second wife was a daughter of William Blount, 4th Lord Mountjoy. The title again suffered forfeiture on Henry's execution, but in 1553 it was recreated for his son Edward (1526-1556). At the latter's death it became dormant in the Courtenay family, till in 1831 a claim by a collateral branch was allowed by the House of Lords, and the earldom of Devon was restored to the peerage, still being held by the head of the Courtenays. The earlier earls of Devon were referred to occasionally as earls of Devonshire, but the former variant has prevailed, and the latter is now solely used for the earldom and dukedom held by the Cavendishes (see **DEVONSHIRE, EARLS AND DUKES OF**, and also the article **COURTENAY**).

DEVON, a south-western county of England, bounded north-west and north by the Bristol channel, north-east by Somerset and Dorset, south-east and south by the English channel, and west by Cornwall. The area, 2,612 sq. mi., is exceeded only by those of Yorkshire and Lincolnshire among the English counties. East to west structural lines dating from Armanian times are dominant features. The high ground to the north of Barnstaple may be considered as an extension of the Quantock hills—Brenon hills—Exmoor forest line, and terminates in Morte point and Buggy point, which face Lundy. Here are exposed a series of slates, grits and limestones considered so characteristic of the county that it was called the Devonian system (q.v.). It represents here the northern rim of a trough in the hollow of which lie the Culm measures of central Devon. The same series appears in the southern rim of the trough in the latitude of Tavistock, but this line is much affected by the granitic mass of Dartmoor, intruded into the Culm and Devonian strata in post-Carboniferous times and subsequently exposed by denudation. The hard core stands out in High Willhays (2,039 ft.), Yes Tor (2,028 ft.) and other peaks. Evidences of Devonian volcanic activity are abundant in the masses of diabase, dolerite, etc., at Bradford and Trusham, south of Exeter, around Plymouth and at Ashprington. Perhaps the most interesting is the Carboniferous volcano of

Brent Tor, near Tavistock. An Eocene deposit, the product of the denudation of the Dartmoor hills, lies in a small basin at Bovey Tracey; it yields beds of lignite and valuable clays.

The eastern side of the county is built of younger rocks, unconformable above the old ones and dipping gently eastwards. The lower and most westerly situated member of the younger rocks is a series of breccias, conglomerates, sandstones and marls which are exposed on the coast by Dawlish and Teignmouth, and extend inland, producing a red soil, past Exeter and Tiverton. A long narrow strip of the same formation reaches out westward on the top of the Culm as far as Jacobstow. Further east, the Dunter pebble beds are represented by the well-known pebble deposit of Budleigh Salterton, whence they are traceable inwards towards Rockbeare. These are succeeded by Keuper marls and sandstones, well exposed at Sidmouth, where the Upper Greensand plateau is clearly seen to overlie them. Greensand covers all the high ground northward from Sidmouth as far as the Blackdown hills. At Beer Head and Amouth the chalk is seen, and at the latter place is a land-ship caused by the springs which issue from the Greensand below the chalk. The lower chalk at Beer has been mined for building stone, and was formerly in considerable demand. At the extreme east of the county, Rhaetic and Liassic beds make their appearance, the former with a "bone" bed bearing the remains of sturgeons and fish.

Local Tertiary movements may account for relics of peneplains, one of which has been located at a height of about 1,000 ft. on the south eastern edge of Dartmoor, and for the north west and north north west systems of faults, which can be traced in several valleys on the eastern edge of Dartmoor. The raised beaches of Hopp's Nose, the Thatcher Stone and other parts of the coast, together with traces of submerged forests, and most of all the long, steep-sided, drowned valleys forming the numerous inlets of the south Devon coast are evidences of recent coastal movements.

The Tamur, which constitutes the boundary between Devon and Cornwall, flows into the English channel. Its estuary has been utilized for the harbours of Plymouth and Devonport. The other principal rivers rise on Dartmoor. These include the Teign, Dart, Plym and Tavy, falling into the English channel, and the Taw flowing north towards Bideford bay. The river Torridge, also discharging northward, receives part of its waters from Dartmoor through the Okement, but itself rises in the angle of high land near Hartland point on the north coast. The lesser Dartmoor streams are the Avon, the Erme and the Yealm, all running south. The Exe rises on Exmoor in Somerset, but the main part of its course is through Devon, and it is joined on its way to the English channel by the lesser streams of the Culm, the Creedy and the Clyst. The Otter, rising on the Blackdown hills, also runs south, and the Axe, for part of its course, divides the counties of Devon and Dorset. The finds made at Oreston, near Plymouth, at Kent's Cavern, near Torquay, at Windmill Hill Cavern, Brixham, and at Cattedown, Plymouth, suggest that these limestone areas with southerly aspects were much favoured by Palaeolithic man. Later settlement seems to have been chiefly on the higher land of the interior. Tumuli, stone circles and alignments are numerous on Dartmoor, and are fairly well distributed over the high land of the county. Hill forts and camps occupy strategic positions, and their distribution suggests that Dartmoor had already lost much of its former significance when they were built. Many are found around the coast guarding routes into the interior.

Roman relics have been found from time to time at Exeter (Isca Dumnoniorum), the only large Roman station in the county.

HISTORY

The Saxon conquest of Devon must have begun some time before the 8th century, for in 700 there existed at Exeter a famous Saxon school. By this time, however, the Saxons had become Christians, and established their supremacy, not by destructive irruptions, but by a gradual process of colonization settling among the native Welsh and allowing them to hold land under equal laws. The final incorporation of the district which is now Devon with the kingdom of Wessex must have taken place about 766. At the beginning of the 9th century Wessex was divided into definite

pages, probably corresponding to the later shires, and the Saxon Chronicle mentions the district by name in 823, when a battle was fought between the Welsh in Cornwall and the people of Devon at Camelford. During the Danish invasions of the 9th century aldermen of Devon are frequently mentioned. In 851 the invaders were defeated by the fyrd and aldermen of Devon, and in 878 they were again defeated with great slaughter. In 1003, in the reign of Ethelred the Unready, the Danes sacked Exeter.

Devon, in the 7th century, formed part of the vast bishopric of Dorchester on Thames. In 705 it was attached to the newly created diocese of Sherborne, and in 910 Archbishop Plegmund constituted Devon a separate diocese, and placed the see at Crediton. About 1030 the dioceses of Devon and Cornwall were united, and in 1049 the see was fixed at Exeter.

William the Conqueror immediately recognized the importance of securing the loyalty of the West by the capture of Exeter. The city withstood an 18 days' siege, and William was only admitted at length upon honourable terms. The many vast fiefs held by Norman barons in Devon were known as honours, chief among them being Plympton, Okehampton, Barnstaple, Harberton and Totnes. The honour of Plympton was bestowed in the 12th century on the Redvers family, together with the earldom of Devon, in the 13th century it passed to the Courtenay family (q.v.), who had already become possessed of the honour of Okehampton, and who in 1335 obtained the earldom. The dukedom of Exeter was bestowed, in the 14th century, on the Holand family, which became extinct in the reign of Edward IV. The ancestors of Sir Walter Raleigh, who was born at Budleigh, had long held considerable estates in the county. In 1204 the inhabitants paid 5,000 marks to have the county disafforested, with the exception of Dartmoor and Exmoor.

Devon had an independent sheriff, the appointment being at first hereditary, but afterwards held for one year only. In 1320 complaint was made that all the hundreds of Devon were in the hands of the great lords who did not appoint a sufficiency of bailiffs for their proper government. The miners of Devon had independent courts, known as stannary courts, for the regulation of mining affairs, the four stannary towns being Tavistock, Ashburton, Chagford, and Plympton. The ancient miners' parliament was held in the open air on Crookern Tor. For mining purposes West Devon is in the Duchy of Cornwall and under the jurisdiction of the Stannary court.

In 1140 the castles of Exeter and Plympton were held against Stephen by Baldwin de Redvers. In the 14th and 15th centuries the French made frequent attacks on the coast. During the Wars of the Roses frequent skirmishes took place between the earl of Devon and Lord Bonville, the respective champions of the Lancastrian and Yorkist parties. In 1470 Warwick and Clarence were pursued as far as Exeter by Edward IV after the battle of "Lose-Cot-Field." Warwick subsequently escaped to the Continent from Dartmouth. Richard III came to Exeter to punish personally those who had inflamed the West against him. Hundreds were outlawed, including the bishop and the dean. Perkin Warbeck besieged Exeter in 1497, and Henry VII came down to thank the citizens for their resistance and to judge the prisoners. Great disturbances in the county followed the inaugural service of Edward VI's prayer book on Whit Sunday, 1549. A priest at Sampford Courtenay was persuaded to read the old Mass on the following day. Swiftly the insubordination spread into a serious revolt, in which the men of Cornwall joined, and Exeter suffered a distressing siege before it was relieved by Lord Russell. On the outbreak of the Civil War the county as a whole favoured the parliament, but the prevailing desire was for peace, and in 1643 a treaty for the cessation of hostilities in Devon and Cornwall was agreed upon. Skirmishes, however, continued until 1646. After the Monmouth rebellion, Judge Jeffreys held a "bloody assize" at Exeter. In 1688 the prince of Orange landed at Torbay and stayed for several days at Forde and at Exeter.

The tin mines of Devon have been worked from time immemorial, and in the 14th century mines of tin, copper, lead, gold and silver are mentioned. At the time of the Domesday Survey the salt industry was important, and there were 99 mills in the

county and its fisheries. From an early period the chief manufacture was that of woollen cloth, and a statute 4 Ed IV permitted the manufacture of cloths of a distinct make in certain parts of Devon. About 1505 Anthony Bonvis, an Italian, introduced an improved method of spinning into the county, and cidee making is mentioned in the 16th century. In 1680 the lace industry was already flourishing at Colyton and Ottery St Mary and flax, hemp and mill were largely produced in the 17th and 18th centuries.

Devon returned two members to parliament in 1290, and in 1295 Barnstaple, Exeter, Plympton, Tavistock, Torrington and Totnes were also represented. In 1831 the county, with its boroughs returned 26 members, but under the Reform Act of 1832 they were reduced to 18. Subsequent bills brought further reductions. The redistribution bill of 1918 left the county with a total of 11 members.

The churches are for the most part of the Perpendicular period, dating from the middle of the 14th to the end of the 15th century. Exeter cathedral is an exception the whole (except the Norman towers) being very beautiful Decorated work. The special features of Devonshire churches are the richly carved pulpits and chancel screens of wood. The largest and the most beautiful screen is that at Hartland (c. 1450). Granite crosses are frequent, the finest being that of Coplestone near Crediton. A number of ancient rude stone crosses stand among the prehistoric ruins remains on the wastes of Dartmoor. Monastic remains are scanty, the principal are those at Tor, Buckfast, Tavistock and Buckland abbey, Buckfast abbey was reconstructed (see Buckfastleton). Among domestic buildings may be mentioned the 14th century parsonage at Little Hempston, the houses of Weir Gifford, Bradley and Dartington of the 15th century, Brindland and Holcombe Rogus (Elizabethan) and Ford (Jacobean). The ruined castles of Okehampton (Edward I), Exeter, with its vast British earthworks, Berry Pomeroy (Henry III, with ruins of a large Tudor mansion) Totnes (Henry III) and Compton (early 15th century), are all interesting.

Climate and Agriculture.—The climate is more humid than that of the eastern or southeastern parts of England. The mean annual temperature somewhat exceeds that of the midlands, but the average summer heat is rather less than that of the southern counties to the east. The air of the Dartmoor highlands is sharp and bracing. Mists are frequent, and snow often lies long. On the south coast frost is little known, and hydrangeas, myrtles, geraniums and heliotrope live through the winter without protection. The climate of the watering places on this coast is very equable, the mean temperature in January being 43° at Plymouth. The north coast, exposed to the storms of the Atlantic, is more bracing, although there also, in the more sheltered nooks (as at Combe Martin), myrtles of great size and age flower freely.

The cultivated area falls a little below the average of the English counties. In 1939 there were, however, about 364,381 ac of rough grazing and 708,272 ac of permanent grass. The arable land was estimated at 415,438 ac. Oats, wheat, barley and root-crops are chiefly grown. The acreage under oats—83,600 ac—was about four times that under barley. Wheat occupied 22,901 ac. The Devon breed of cattle is well adapted both for fattening and for dairy purposes, while sheep are kept in great numbers on the hill pastures (973,209 in 1939). Devon is specially famous for clotted cream and junket. The bulk of the acreage under green crops is occupied by turnips and swedes and mangolds at 22,335 ac and 14,984 ac respectively. Orchards occupy a large acreage, 21,400 ac in 1939, and consist chiefly of apple trees, mainly for the manufacture of cider. The National Trust owned about 2,250 ac in the county in 1942 and had a 500-year lease of 10,000 acres in Exmoor at a nominal rent.

Fisheries.—Large quantities of the pichard and herrings caught in Cornish waters are landed at Plymouth. Much of the fishing is carried on within the three-mile limit, and it may be asserted that trawling is the main feature of the Devonshire industry, whereas seining and driving characterise that of Cornwall. Pilchard, cod, sprats, brill, plaice, soles, turbot, shrimps, lobsters, oysters and mussels are met with, besides herring and mackerel,

which are fairly plentiful. After Plymouth the principal fishing station is at Brixham, but there are many lesser stations.

Other Industries.—The principal industrial works are the various government establishments at Plymouth and Devonport. Among other industries may be noted the lace works at Tiverton, the manufacture of pillow lace for which Honiton and its neighbourhood has long been famous, and the potteries and terra cotta works of Bovey Tracey and Watcombe. Woollen goods and seiges are made at Buckfastleigh, while Plymouth produces chemical manure, soap, starch, blue and black lead.

Minerals.—Silver lead was formerly worked at Combe Martin, near the north coast, and elsewhere. Tin has been worked on Dartmoor (in stream works) from an unknown period. Copper was not much worked before the end of the 18th century. Tin occurs in the granite of Dartmoor, and along its borders, and especially, with zinc and iron, around Tavistock, which has the Devon Great Consols mine within 4 mi., which from 1843-71 were the richest of copper mines. But Devonshire mining is affected by the same causes as that of Cornwall. The quantity of ore has greatly diminished and the cost of raising it from the deep mines prevents competition with foreign markets. In many mines tin underlies the general depth of the copper, and is worked when the latter has been exhausted. Great quantities of refined arsenic have been produced at the Devon Great Consols mine, by elimination from the iron pyrites contained in the various lodes. Manganese occurs in the neighbourhood of Exeter, in the valley of the Teign and in north Devon, but the most profitable mines are in the Tavistock district. There are two mines for tungsten ores, at Gunnislake, near Tavistock, and Marytavy.

The other mineral productions of the county consist of marbles, building stones, slates and potters' clay. The granite of Dartmoor is much quarried near Princetown, near Moreton Hampstead on the northeast of Dartmoor, and elsewhere. Hard traps, which occur in many places, are also much used for building, as are the limestones of Buckfastleigh and of Plymouth. The Roborough stone, used from an early period in Devonshire churches, is found near Tavistock, and is a hard porphyritic elvan, taking a fine polish. Excellent roofing slates occur in the Devonian series round the southern part of Dartmoor. The chief quarries are near Ashburton and Plymouth (Cann quarry). Potters' clay is worked at King's Teignton, whence it is largely exported, at Bovey Tracey, and at Watcombe. The Watcombe clay is of the finest quality. China clay or kaolin is found on the southern side of Dartmoor, at Lee Moor, and near Lustleigh. There is a large deposit of amber close to Ashburton.

Communications.—The main line of the G.W. railway, entering the county in the east from Taunton, runs to Exeter, skirts the coast as far as Teignmouth, and continues a short distance inland by Newton Abbot to Plymouth, after which it crosses the estuary of the Tamar by a great bridge to Saltash in Cornwall. Branches serve Torquay and other seaside resorts of the south coast, and among other branches are those from Taunton to Barnstaple, and from Plymouth northward to Tavistock and Launceston. The main line of the Southern railway between Exeter and Plymouth skirts the north and west of Dartmoor by Okehampton and Tavistock. A branch from Yeoford serves Barnstaple, Ilfracombe, Bideford and Torrington. The branch line to Princetown from the Plymouth Tavistock line of the G.W. company in part follows the line of a very early railway—that constructed to connect Plymouth with the Dartmoor prison in 1819-25, which was worked with horse cars. The only waterways of any importance are the Tamar, which is navigable up to Gunnislake (3 mi S.W. of Tavistock), and the Exeter ship canal, noteworthy as one of the oldest in England, for it was originally cut in the reign of Elizabeth.

The area of the administrative county is 2,582 sq mi. Pop (est. 1938) 741,660. Wartime movements caused by evacuation from dangerous areas raised the population of Devon by 10% between Sept. 1939 and Feb. 1941. There were in 1943 ten municipal boroughs, two county boroughs, and 21 urban districts.

Bibliography.—T. Westcott, *Survey of Devon*, written about 1630, and first printed in 1845; J. Prince, *Worthies of Devon* (Exeter, 1701).

The Old Red reappears in the Cheviots (where it is largely igneous) and on the margins of the Forth and Clyde syncline. Here both Devonian and Dittonian are recognizable by their fossils. The former follows the Silurian conformably, but is frequently separated from the Dittonian by an unconformity. The latter includes conglomerates, lavas, tuffs and lacustrine deposits, with *Mesacanthus*, *Cephalaspis lyelli* and *Pteraspis*.

On the Moray Firth, in Caithness, the Orkneys and Shetlands are strata intermediate in age between the Dittonian and Upper Old Red, which are classed as Middle Old Red, but they are more allied to the Upper than to the Lower. In Caithness an unfossiliferous basement series is followed by conglomerate, and arkose, and then by thick beds of bituminous and calcareous flags and sandstones. Characteristic fossils are *Thursus*, *Dipterus valencienensis*, *Mesacanthus*, *Coccosteus decipiens*, *Pterichthys*, *Estheria* and *Palaeospondylus*. A higher horizon, the John o' Groat beds, has a distinct fauna.

The Upper Old Red sandstone of Scotland overlies unconformably the Lower Old Red in the south and the Middle in the north. There are two horizons. The Lower, the Nairn sandstone, contains *Psammosteus tessellatus*, *Astrololopus maxima*, and the Upper, the Alves or Scaat Craig beds, has *Psammosteus pusillatus*, *Bothriolepis major* and *Holopterychus nobilissimus*. Only one form, *H. decoratus*, is common to both.

The Devonian appears to occur in Norway and the Dittonian in Spitzbergen. Upper Old Red with *Holopterychus* and *Archaeopterus* is found in Bear Island, associated with thin coals. In Nova Scotia and New Brunswick the Dittonian with *Cephalaspis* and *Pteraspis* rests unconformably on the Silurian. The Upper Old Red also occurs in the latter, and in New York State it is represented by the Oneonta beds with *Estheria*, and the Catskill with *Bothriolepis* and *Holopterychus*.

In Antarctica, the Upper Old Red age of the Beacon sandstone is indicated by the same two forms.

The marine succession sometimes includes continental intercalations, and even in the marine beds, different facies occur according to the varying conditions under which deposition took place.

Nearest to land were the brackish water and littoral deposits, which may show by red or purple coloration the desert origin of their materials. In deeper water and farther from shore terrigenous mud, now shale or slate, was laid down, and, where conditions were favourable, coral reefs or lenticular limestones were formed. At still greater depths and distance from land, calcareous ooze accumulated with thin shelled molluscs, goniatites and simple corals. The position of these different facies was modified by changes in the level of the sea and floor movements. To the former has been attributed the recession of the sea throughout the Northern Hemisphere at the beginning of the period. The shore line of the northern continent then passed south of Ireland, through Cornwall and south Devon, entered northern France near Boulogne, passed by way of Fepin to the north of the massives of the Rhine and Harz, and of Bohemia, then southward to the Dniester region and central Russia, and north-westward to the White sea. In the Middle Devonian an important advance of the sea began and reached its maximum at the close of the Middle or beginning of the Upper Devonian. The shore line of the northern continent then passed across south Ireland, Pembrokehire, the Bristol channel, Middlesex, north Belgium, the Baltic, Finland, and Lapland. In the later Upper Devonian there was a new retreatment of the sea, and the shore line moved southward again—in some places nearly as far as before, in others, as in Bohemia, still farther.

Parallel to the continental shores, the weight of the terrigenous sediments and accumulated limestones caused a sag of the sea bottom in "geosynclines," and this permitted a still heavier accumulation of deposits.

CENTRAL EUROPE

It is in the Palaeozoic massive of the Ardennes and the Rhineland that the marine Devonian has been most studied. There it has been thrown by the subsequent Armorican movements into

folds dipping to the south, and it is in the troughs of these folds that the Middle and Upper Devonian are found as outliers in the Lower. On the Meuse are two main synclines, that of Namur in the north and that of Dinant in the south. On the southern limit of the latter the base of the system is formed by a conglomerate and arkose. These are covered by the Mondreputis shales with *Spiserius sulcatus* (*mercurius*) which are correlated with the Devonian. They are succeeded by the mottled Oignies shales containing *Pteraspis* and, therefore, presumably Dittonian.

The next horizon, the Siegenian is represented in Belgium by the Anor grits and the Montigny Greywacke, and in the Rhineland by the Taunus quartzite and the Hunsrück slates, or their equivalents, the Siegen slates. Then follows the Emsian with, on the Meuse, the Red shales of Vireux, and on the Rhine, the Lower Coblenz beds. A higher horizon is that of the Hierges Greywacke corresponding to the Coblenz quartzite and Upper Coblenz beds.

On the north of the Dinant syncline and near the former coastline, the Lower Devonian is represented only by the Burnot conglomerate. In the south eastern Harz, the Lower Devonian has a deep water ("Hercynian") facies with *Spiserius togatus*, *Sp. hercyniae*, *Capulus* and *Phacops secundus*. The same fauna appears in the Konjprus limestone of Bohemia, Barrande's F₂ zone.

The Middle Devonian is divided into the Eifelian and the Givetian. At the base of the former is the *Spiserius caltrugatus* zone. Then follow the *Calcolia* Beds. The Givetian is distinguished by the large brachiopod *Stringocephalus*. The Middle Devonian is usually more calcareous than the Lower and the Givetian than the Eifelian. In the Namur syncline the *Calcolia* beds rest directly, except for a conglomerate, on the Silurian. Still further north in Brabant, the Eifelian is absent and the Givetian is only separated from the Silurian by a similar conglomerate. In south-west Westphalia the Eifelian and Lower Givetian consist of sandy clays often more or less calcareous. They have yielded plants and *Archaeonodon* and were probably laid down in fresh water. Similarly in the Boulonnais, sandy beds with plants seem to represent the Eifelian as they are overlaid by a limestone with *Stringocephalus*. In the southern Rhineland the middle division consists of deep water shales and limestones. In Bohemia the Eifelian is represented by Barrande's zones G₁, G₂ and G₃ deep water limestones, the Givetian, on the other hand, by the zones H₁, H₂ and H₃ shales and sandstones with plants and *Stringocephalus*. The deep water Middle Devonian has been zoned by species of goniatites. Of these, *Manticoceras* and *Tornoceras* are characteristic of the Upper Givetian.

The Upper Devonian has two main divisions, the Frasnian and the Famennian. The former commences by limestone with *Buchiola retrostrata*, succeeded by the Budesheim or Matagne shales, with characteristic goniatites, including *Manticoceras tumescens* and *Tornoceras simplex*, and the bituminous Kellwas limestone. Other Frasnian fossils are *Spiserius verneuli*, which extends through all the Upper Devonian and *Phylloporites*. The deep-water Famennian is characterized by the prevalence of the *Clymenia* group. In the lower Famennian it is accompanied by the goniatite genus *Cheiloceras* which marks the horizon of the Neiden shales. The Cypridina shales, laid down in shallower water, contain the small bivalve crustacean *Entomus*—formerly *Cypridina serrato-strata* in large numbers. In the Namur syncline continental conditions prevailed in the upper Famennian with *Holopterychus* and *Archaeopterus*, though in some places littoral forms like *Cucullaea hardingi* are found. In the Boulonnais the *Stringocephalus* limestone is followed by fossiliferous Frasnian limestone, and then reddish shales with *Spiserius verneuli* and sandstone comparable with that of Condor. In Bohemia there is no evidence of the Upper Devonian, but in the eastern Alps the whole formation is well represented.

In the south west of England, the Devonian is also strongly folded. The lowest rocks in north Devon and west Somerset are the continental Foreland grits—red sandstones and conglomerates, of which the base is not seen as they form an anticline, they contain only scanty indeterminate fragments of fish and plants. The succeeding Lynton beds appear to include Dittonian beds, with *Pteraspis*, and Siegenian with *Spiserius primaevus* and *Sp.*

Typical Fossils		Meuse Valley		Rhineland	Bohemia	North Devon	South Devon and Cornwall	New York State (Marine beds)
Concentual	Marine	Dinant syncline	Dinant syncline	Various localities

Downtonian	"Anaspidea" <i>Cephalopodus lyelli</i>	Montreupits Mayers Arkose Frasnian conglomerate	Absent	Quartzites	(?) Fenecland grits			Forstbach arenaceous shales

hystericus They are overlaid by grits resembling the Forelands, and called collectively the Hangman grits The lower beds, the Transhove grits, have yielded no fossils, but at a higher level are sandstones and shales with plant remains and a scyle of *Coccos leus*, followed by littoral beds with casts of *Myalina*, *Cucullaea* and *Naticopsis*, and by calcareous grits with *Strigoccephalus* which must be Givetian Above these is a thick succession of grits, slates and limestones, the Ilfracombe beds They include coral reefs with *Cyathophyllum* (*Phacelophyllum*) *caespitosum*, *Endophyllum*, and *Pachypora cervicornis* At a somewhat higher horizon occur *Helophyllum hebanthoides* and *Spirifer verneuili* The latter, at least, indicates the Upper Devonian The higher beds, which are arenaceous, are succeeded by the smooth Morte slates with *Spirifer verneuili*, and then by the Pickwell Down sandstone, a continental deposit corresponding to the Cornish

At the base is a bed of volcanic ash associated with fish remains including *Bothriolepis* and *Holoptychius* The Pickwell Down sandstone passes up into the littoral Baggy and Marwood beds These contain two fossils *Cucullaea unilateralis* and *Ptychopteria dammonensis*, also found in the marine beds in the Upper Old Red of Pembrokeshire and the Coomhola grits of Ireland Then follow the Pilton beds which extend up into the Carboniferous, which occupies a great syncline crossing Devonshire from east to west Beyond this the Devonian reappears in Cornwall and south Devon In south west Cornwall it rests on the Silurian, but the rocks are so dislocated that it is impossible to say whether the formations are conformable or not The Downtonian may be represented by the Portscatho beds, arenaceous slates which pass up into the smooth Falmouth slates, apparently identical with the Dartmouth slates that form an anticline traversing south Devon and Cornwall They contain *Cephalaspis* and *Pteraspis*, and appear to be fresh water deposits of Diltonian age, except in south Devon, where the presence of *Bellerophon* and *Loxonema* indicates brackish conditions The succeeding Meadfoot beds have yielded *Spirifer primævus*, *Sp. hystericus*, and other marine fossils of Siegenian age Then follow the Staddon grits which include beds of Emsian age, with *Tropidolepis rhenanus* and others at the base of the Middle Devonian, with *Spirifer cultrigugatus*

Next are slates and slaty limestones with *Calceola* There are also great developments of limestone near Plymouth and Torquay in which both Middle and Upper Devonian are represented, for the fossils include *Spirifer curvatus*, *Strigoccephalus*, *Spirifer verneuili* and *Rhynchonella* (*Hypothyris*) *cuboides* The Budeheim horizon is found at Trevona bay, in North Cornwall, and Saltern cove, in South Devon, that of the Nehden shales at Port Quin in north Cornwall Famennian horizons are also represented by strata with *Clymenia*, *Entomis serrato-strata* and *Styloloma* The Devonian, south of the syncline, is overlapped by beds high up in the Carboniferous limestone, and the overlap increases to the south, but this relation is obscured by overthrusts of the Devonian over the Carboniferous

Deep under London both continental and marine Upper Devonian are met with Many horizons of the Devonian occur in American folds of the north-west of France In the Devonian rocks of southern Europe, the Lower Devonian and Eifelian are represented by limestones and dolomites laid down at moderate depths, the Givetian and Upper Devonian by limestone accumulated in deeper water, with pale reddish or greenish tints, believed to characterize calcareous oozes

In the Baltic and adjoining areas the Downtonian succeeds to the Silurian, but there is then a break (without unconformity) followed by typical Middle Old Red This is, however, succeeded by marine Frasnian with *Spirifer Anosofi*, an eastern form In the Famennian, continental conditions returned Further south and east, however, there are marine intercalations, and in central Russia and the Urals, the Famennian is wholly marine Both the Scotch zones of the Upper Old Red are represented in north eastern Europe—the Naurn sandstone by the Wenden deposits on the An in Livonia, and the Alves by those of the Sjass river near Leningrad,

NORTH AMERICA

The seas on the east and west of the position of the present continent of North America were regions of sedimentation and subsidence, and from them the marine transgression spread over the intervening area The succession in New York State where the beds have been but little disturbed is given in the table The Helderbergian consists of deep sea limestones similar to those of the Lower Devonian of Bohemia It rests conformably on the Silurian, and is succeeded in the east by the Oriskany sandstone which occurs discontinuously as far west as the Mississippi It resembles the Lower Devonian of the Meuse and Rhine As the sea deepened and extended, the Onondaga limestone was laid down, which the presence of *Spirifer acuminatus* (*cultrigugatus*) would place low in the Eifelian The limestone is represented by shales in the south, and is later itself replaced by the Marcellus shales which are correlated by their goniatites with the Wassenbach shales of Europe They are followed by the more calcareous Hamilton shales, with increasing depth of the sea, which, at the end of the Middle Devonian, occupied 38% of the area of the present continent Although the Hamilton was contemporaneous with the Givetian of Europe, the fauna is quite distinct from that of the *Strigoccephalus* beds, which is, however, found in Manitoba The affinities of the Hamilton are with southern areas

The Upper Devonian commences with the Tully limestone, the equivalent of the Iberr limestone of Europe, followed by the Genesee, bituminous and pyritous shale and the Portage beds with three facies, in the west the deep water Naples shales with *Gephyroceras intumescens*, in the east the Ithaca shales and sandstones with *Tropidolepis carinatus*, also found in the Hamilton, and still further east the Oneonta The Famennian is represented by the continental Catskill beds and the marine Chemung, with *Spirifer verneuili* In Montana shaly marls with *Clymenia* and *Cheloceras* indicate deeper water

SOUTH AMERICA AND AFRICA

The most complete succession is found in Bolivia Resting unconformably on the Ordovician are (1) the Icla sandstone with Silurian fossils near its base, (2) the sandy Icla shales, (3) the Huampampa sandstone, and (4) the Sicasica beds The fauna of the Icla shales and the Huampampa sandstone is widespread through the Southern Hemisphere—in Parana (Brazil), the Argentine, the Falklands, and the Bokkeveld beds, which overlie the Table Mountain sandstone in South Africa *Spirifer antarcicus*, *Chonetes falklandicus*, and *Leptocoelia fabelites* are found throughout The fauna of the Sicasica beds is essentially Middle Devonian with some lower forms It has affinities with the Hamilton The Devonian fossils of the Sahara are related to North and South American forms The Devonian of the Gold Coast appears to be a littoral facies of the Hamilton, and is linked with the Sicasica by *Hemalonotus dehayi*

The older southern fauna extending from the Sicasica shales to the Bokkeveld beds may be placed at the base of the Middle Devonian or high in the Lower Its special characters, the scarcity of corals and bryozoa, the number of discoid brachiopods, the absence of limestones and the dark grey, blue and green colouring have been attributed to polar conditions, a view supported by the occurrence of glaciation in the Table Mountain sandstone Some indeterminate lamellibranchs at the base of the latter may be Silurian like the Icla sandstone, not Devonian The Bokkeveld passes up into the Witteberg, a series of sands and quartzites containing indistinct plant remains, which are believed to represent a passage into the Carboniferous

Except for the Caledonian movement at its commencement the Devonian was a time of comparative quiet, but of slow movements, affecting the distribution of land and water and causing unconformities and overlaps

The granite or granodiorite intrusions of the late Silurian in the north of Great Britain continued into the early Devonian They were associated with volcanic activity, mainly of an andesitic or basaltic character, and minor intrusions of similar composition In Devon and Cornwall there were, in later Devonian times, submarine outpourings of spilitic pillow lavas accompanied by tuffs

They resemble the contemporaneous schists of Germany

ECONOMIC PRODUCTS

There are iron ores of some importance mostly occurring as replacements of limestone. The metalliferous lodes of Cornwall and Devon are largely in rocks of Devonian age, but are the result of Armorican igneous activity. The oil of Ontario has its source in Middle Devonian shales, while that of New York and Pennsylvania may be derived from the black shales of the Upper Devonian.

Surv., 1912), also numerous papers by J. M. Clarke, E. M. Kindle and C. Schuchert (J. W. Ev.)

DEVONPORT, a seaport, garrison and market town of Devonshire, England, served by the S.R. and G.W.R. Devonport is the seat of one of the royal dockyards, and an important naval and military station. It is situated on the west of Plymouth and the east shore of the Hamoaze (or estuary of the Tamar and the Lynher) at its entrance into Plymouth sound. The "three towns" of Devonport, East Stonehouse (in the middle) and Plymouth now form one unit. Devonport is connected with East Stonehouse by a bridge over Stonehouse pool, an inlet of Plymouth harbour. A ferry across the Hamoaze connects it with the wooded peninsula of Mount Edgumbe on the Cornish shore, and river steamers ply to Saltash and St. Germans higher up the river, at Morice Town a floating bridge connects with Tor point in Cornwall. Devonport, which owes its origin to the royal dockyard on the Hamoaze, begun in 1689 and now known as the "South Yard," was called Plymouth Dock until 1820, when it changed its name to Devonport. The "old town" which grew up around the dockyard is marked by the fortified "lines," known as the Brickfields, now mostly demolished and providing an open space and parade grounds, with Devonport park (37 ac.) at the northern end. Beyond the districts of Stoke or Stoke Damerel, Ford and Morice Town on the Hamoaze to the north. Stoke Damerel, a residential suburb, is the mother parish of Devonport and contains the old parish church of St. Andrew, originally Perpendicular with a 15th century tower. Morice Town is a rapidly growing district which has arisen round Keyham Steam yard, now the "North Yard," the second of the government dockyards, established in 1846, with its own iron and brass foundries, machinery shops, engineer students' shops, and docks and basins along the Hamoaze. St. Budeaux to the north was joined to Devonport in 1914. There are several points of elevation in Devonport, and the prospect from Mount Wise at the southern extremity of the old town overlooking the harbour and its shore is one of the finest on the south coast. Here, together with a naval signalling station, is the residence of the commander-in-chief or port admiral, of the Plymouth naval command, as well as the headquarters and residence of the general officer commanding the southwestern military area. A national memorial to Capt. R. T. Scott and his four companions of the South Polar expedition was erected there in 1925. From here the Regent, George Square and other naval and military barracks and quarters extend northwards to the St. Budeaux barracks and naval armament depot at Bull Point. Stonehouse pool is lined with the new quays, wharves and boat-building yards, at the northern end is the military hospital (1797), facing the naval hospital in Stonehouse. Among the public buildings and institutions of Devonport are the town hall (1822), market house (1852) and public library, close to which is a granite column, built 1824, commemorating the renaming of the town, the Royal United Services and the Royal Dockyard orphanages, and the Prince of Wales's hospital buildings and a Sailors' Rest. Devonport is a station of the western division of the home fleet. The admiralty moorings in the Hamoaze extend for 3 mi. Between the South and the North yards is the Gun Wharf (c. 21 ac.) on the Hamoaze, first laid out in 1718, with armoury, storehouses, etc., the three establishments, with the naval bar-

racks, known as H.M.S. "Drake," being connected by a tunnel. In 1907 an extension of 118 ac. was made to the North yard, including a tidal basin of 10 ac. and closed basin of 353 ac. (with coaling depot and direct access to the Hamoaze), each with a depth of 32 ft. at low water springs, and affording access to large new graving docks of 700-800 ft. length. The South yard also contains a sail factory and a ropery where a large part of the hempen ropes used in the navy are produced. By the Reform act of 1832 Devonport became a parliamentary borough including East Stonehouse and returning two members. It was incorporated in 1837. In 1914 it amalgamated with Plymouth. The ground on which its stands is largely the property of the St. Aubyn family (Baron St. Leon), as lords of the manor.

DEVONPORT, EAST AND WEST, a town on the N. coast of Tasmania, Australia, on both sides of the mouth of the river Mersey, about 30 mi. N.W. of Launceston. Pop. 5,151. Devonport ranks as the third port in Tasmania. It is the centre of an important dairy, potatoes and timber area. The limestone used in the Newcastle steel mills is obtained nearby.

DEVONSHIRE, EARLS AND DUKES OF The Devonshire title, now in the Cavendish family had previously been held by Charles Blount (1563-1606), 8th Lord Mountjoy, great-grandson of the 4th Lord Mountjoy (d. 1534), the pupil of Erasmus, he was created earl of Devonshire in 1601 for his services in Ireland (1600-03), but the title became extinct at his death. In the Cavendish line the 1st earl of Devonshire was William (d. 1626), second son of Sir William Cavendish (q.v.), and of Elizabeth Hardwick, who afterwards married the 6th earl of Shrewsbury. He was created earl of Devonshire in 1618 by James I., and was succeeded by William, 2nd (1591-1628), and the latter by his son William (1617-1684).

WILLIAM CAVENDISH, 1st duke of Devonshire (1640-1707), English statesman, eldest son of the earl of Devonshire last mentioned, was born on Jan. 25, 1640. In 1661 he entered parliament, and soon showed himself a determined and daring opponent of the general policy of the court. In 1678 he was one of the committee appointed to draw up articles of impeachment against the lord treasurer Danby. In 1679 he was re-elected for Derby, and made a privy councillor by Charles II., but he withdrew from the board with his friend Lord Russell, when he found that the Roman Catholic interest uniformly prevailed. He carried up to the House of Lords the articles of impeachment against Lord Chief-Justice Scroggs, and when the king declared his resolution not to sign the bill for excluding the duke of York, afterwards James II., he moved in the House of Commons that a bill might be brought in for the association of all his majesty's Protestant subjects. He appeared in defense of Lord Russell at his trial, and after his condemnation he offered to exchange clothes with him in the prison, remain in his place, and so allow him to effect his escape. In Nov. 1684 he succeeded to the earldom. He opposed arbitrary government under James II. with the same consistency and high spirit as during the previous reign. An imprudent quarrel at court was punished by a fine of £30,000 which he could not pay, and he was in prison for some time. After his discharge the earl occupied himself with the erection of a new mansion at Chatsworth designed by William Talman, with decorations by Verrio, Thornhill and Grinling Gibbons. The revolution again brought him into prominence. He was one of the seven who signed the original paper inviting the prince of Orange from Holland, and was the first nobleman who appeared in arms to receive him at his landing. He received the order of the Garter, and was made lord high steward of the new court. In 1690 he accompanied King William on his visit to Holland.

He was created marquis of Harrington and duke of Devonshire in 1694.

He had married in 1661 the daughter of James, duke of Ormonde, and was succeeded by his eldest son William as 2nd duke, and by the latter's son William as 3rd duke (vicerey of Ireland, 1737-44). The latter's son William (1720-64) succeeded in 1755 as 4th duke, he married the daughter and heiress of Richard Boyle, earl of Burlington and Cork, who brought Lismore castle and the Irish estates into the family, from Nov. 1756 to May 1757 he

was prime minister, mainly in order that Pitt, who would not then serve under the duke of Newcastle, should be in power. His son William (1748-1811), 5th duke, was the husband of the beautiful Georgiana Spencer, duchess of Devonshire (1757-1806), and of the intellectual Elizabeth Foster, duchess of Devonshire (1757-1824), both of whom Gainsborough painted. His son William, 6th duke (1790-1858), died unmarried. The title passed in 1858 to his cousin William (1808-91), 2nd earl of Burlington, as 7th duke, who, in 1829 was second wrangler at Cambridge, first Smith's prizeman and eighth classic, and subsequently became chancellor of the university.

DEVONSHIRE, SPENCER COMPTON CAVENDISH, 8TH DUKE OF (1833-1908), born at Holker Hall on July 23, 1833, was the son of the 7th duke (then earl of Burlington) and his wife Lady Blanche Howard (sister of the earl of Carlisle). In 1854 Lord Cavendish, as he then was, took a second class in the mathematical tripos at Trinity college, Cambridge, in 1856 he was attached to the special mission to Russia for the new tsar's accession, and in 1857 he was returned to parliament as Liberal member for North Lancashire. At the opening of the new parliament of 1859 the marquis of Hartington (as he had then become) moved the amendment to the address which overthrew the government of Lord Derby. In 1862 he visited the United States, and in 1863 he became first lord of the Admiralty, and then under secretary for war in Lord Palmerston's government, and on the formation of the Russell-Gladstone administration at the death of Lord Palmerston he entered it as war secretary. He retired with his colleagues in July 1866 and used his comparative leisure to visit Germany and to meet Bismarck. On Gladstone's return to power in 1868 he became postmaster general, an office which he exchanged against his own inclination, in 1871, for that of secretary for Ireland. When Gladstone, after his defeat and resignation in 1874, temporarily withdrew from the leadership of the Liberal Party in Jan 1875, Lord Hartington reluctantly accepted the position of Liberal leader in the House of Commons, Lord Granville being leader in the Lords. W. E. Forster, who had taken a much more prominent part in public life, was the only other possible nominee, but he declined to stand. The new leader of the House was a moderate critic of Disraeli's foreign policy in the near East, but emphatically condemned the conduct of Indian affairs which led up to the first Afghan War of 1878. After the Conservative defeat in the general election of 1880, the queen, in strict conformity with constitutional usage (though Gladstone himself thought Granville should have had the preference), sent for him as leader of the opposition, but Hartington declined the request to form a government, in view of Gladstone's position in the party. Hartington joined the new Gladstone government as secretary of State for India, from which office, in Dec 1882, he passed to the War Office. His administration was responsible for the expeditions of Gen Gordon and Lord Wolsley to Khartoum.

He shared the responsibility for sending Gordon to evacuate the Sudan, but it must be said that he repeatedly warned the cabinet of the urgency of the Wolsley relief expedition, and threatened resignation when a decision was delayed. In June 1885 he resigned along with his colleagues, and in December was elected for the Rossendale division of Lancashire, created by the new Reform Bill. Immediately afterwards Gladstone's conversion to home rule for Ireland forced on Lord Hartington the great political decision of his life. His refusal to follow his leader in this course inevitably made him the chief of the new Liberal Unionist Party. He moved the first resolution at the famous public meeting at the opera house in the Haymarket (April 14, 1886), when Lord Salisbury was also on the platform. In the House of Commons Hartington moved the rejection of Gladstone's bill on the second reading. During the electoral contest which followed, no election excited more interest than Lord Hartington's for the Rossendale division, where he was returned by a majority of nearly 1,500 votes.

In the new parliament he held a position much resembling that which Sir Robert Peel had occupied after his fall from power, the leader of a small, compact party, the standing and ability of

whose members were out of all proportion to their numbers, generally esteemed and trusted by and any other man in the country yet in his own opinion forbidden to think of office. Lord Salisbury's offers to serve under him as prime minister (both after the general election and again in Jan 1887, when Lord Randolph Churchill resigned) were declined, and Lord Hartington continued to discharge the delicate duties of the leader of a middle party. It was not until 1895, when the differences between Conservatives and Liberal Unionists had become attenuated by changed circumstances, and the habit of acting together, that the duke of Devonshire, as he had become by the death of his father in 1891, entered Lord Salisbury's third ministry as president of the council, an office which carried at that time the responsibility for education. He also presided over the cabinet committee of defence. In 1892 he succeeded his father as chancellor of the University of Cambridge. In that year too he married the widow of the 7th duke of Manchester.

He continued to hold the office of lord president of the council till Oct 3, 1903, when he resigned on account of differences with Balfour over the latter's attitude towards free trade. As Chamberlain had retired from the cabinet, and the duke had not thought it necessary to join Lord George Hamilton and Ritchie in resigning a fortnight earlier, the defection was unanticipated, and was sharply criticized by Balfour. But the duke had come to the conclusion that while he himself was substantially a free trader, Balfour did not mean the same thing by the term. He necessarily became the leader of the Free Trade Unionists who were neither Balfourites nor Chamberlainites, and his weight was thrown into the scale against any association of Unionism with the constructive policy of tariff reform, which he identified with sheer protection. A struggle at once began within the Liberal Unionist organization between those who followed the duke and those who followed Chamberlain, but the latter were in the majority, and the duke resigned his chairmanship of the Liberal Unionist Association (May 1904), and became president of the new organization, the Unionist Free Food league and the Unionist Free Trade club. In the autumn of 1907 his health gave way, and he went to Egypt. He died on his way home at Cannes on March 24, 1908. He had a firm friendship with the prince of Wales, afterwards Edward VII.

There was no issue of his marriage, and his successor as 9th duke was his nephew VICTOR CHRISTIAN CAVENDISH (1868-1938), who had been Liberal Unionist member for West Derbyshire since 1891, and was treasurer of the household (1900-03), financial secretary to the Treasury (1903-05), civil lord of the Admiralty (1915-16) and governor general of Canada (1916-21), in 1892 he married a daughter of the marquess of Lansdowne. He was succeeded as 10th duke by his son, EDWARD WILLIAM SPENCER CAVENDISH (1895-1950).

See Bernard Holland, *Life of the 8th Duke of Devonshire* (1911).

DEVRIENT, the name of a family of German actors.

LUDWIG DEVRIENT (1784-1832), born in Berlin on Dec 15 1784, was the son of a silk merchant. He was apprenticed to an upholsterer, but joined a travelling theatrical company, and first appeared on the stage at Gera in 1804 as the messenger in Schiller's *Braut von Messina*. Eventually he obtained a permanent engagement at the ducal theatre in Dessau, where he played till 1809. He then went to Breslau for six years. His success in Shakespeare was such that Ifland feared for his own reputation, but generously recommended Devrient as his successor. On Ifland's death Devrient was summoned to Berlin, where for 15 years he was the popular idol. He died there on Dec 30, 1832. He was equally good in comedy and tragedy. Falstaff, King Lear, Franz Moor, Shylock and Richard II were among his best parts. Karl von Holtei in his *Reminiscences* has given a graphic picture of his acting.

See F. Funck, *Aus dem Leben Zweier Schauspieler, Iflands und Devrients* (Leipzig, 1838); H. Smidt in *Devrient Novellen* (3rd ed 1882); R. Springer, *Devrient und Hofmann* (1873); Eduard Devrient, *Geschichte der deutschen Schauspielkunst* (Leipzig, 1867); G. Altmann, *Ludwig Devrient* (1926).

Three of the nephews of L. Devrient played an important part in the history of the German stage.—KARL AUGUST DEVRIENT

(1797-1872) was born at Berlin on April 5, 1797. He made his first appearance on the stage in 1819 at Brunswick. In 1821 he received an engagement at the court theatre in Dresden, where, in 1823, he married Wilhelmine Schroder. In 1835 he joined the company at Karlsruhe, and in 1839 that at Hanover. His best parts were Wallenstein and King Lear. He died on April 5, 1872.

His brother, PHILIPP EDUARD DEVRIENT (1801-1877), born at Berlin on Aug. 11, 1801, was from 1844 to 1846 director of the court theatre in Dresden. Appointed to Karlsruhe in 1852, he began a thorough reorganization of the theatre, and not only raised it to a high position, but enriched its repertory by many noteworthy librettos, among which *Du Gaiest des Augenblicks* and *Erranden* are the best known. But his chief work is his history of the German stage *Geschichte der deutschen Schauspielkunst* (Leipzig, 1849-74). He died on Oct. 4, 1877.

The youngest and the most famous of the three nephews of Ludwig Devrient was GUSTAV EMIL DEVRIENT (1803-1872), born in Berlin on Sept. 4, 1803. He made his first appearance on the stage in 1821, at Brunswick, as Raoul in J. C. F. von Schiller's *Jungfrau von Orleans*. After a short engagement in Leipzig, he received in 1829 a call to Hamburg, but after two years accepted a permanent appointment at the court theatre in Dresden, to which he belonged until his retirement in 1868. He acted several times in London where his Hamlet was considered finer than John Philip Kemble's or Edmund Kean's. He died on Aug. 7, 1872.

OTTO DEVRIENT (1838-1894), another actor, born in Berlin on Oct. 3, 1838, was the son of Philipp Eduard Devrient. He joined the stage in 1856 at Karlsruhe, and acted successively in Stuttgart, Berlin and Leipzig, until he received a fixed appointment at Karlsruhe in 1863. In 1873 he became stage manager at Weimar, where he gained great praise for his *mise en scène* of Goethe's *Iphigeneia*. After being manager of the theatres in Mannheim and Frankfurt, he retired to Jena. In 1884 he was appointed director of the court theatre in Oldenburg, and in 1889 director of dramatic plays in Berlin. He died at Stettin on June 23, 1894.

DE VRIES, HUGO

method of producing new forms was named mutation, as distinct from Charles Darwin's natural selection. He showed that while species vary through natural selection, new species and varieties arise suddenly through mutation. He visited the United States to investigate the behaviour of *Oenothera* in its natural environment. After his retirement in 1918 from the University of Amsterdam he made his residence in Lunteren, where he continued his experimental work in producing new forms through mutation or culture. He died on May 21, 1935. His best known works are *Intracelluläre Pangenesis* (1889), *The Mutation Theory* (Ger. ed., 1900-03; Eng. trans., 1910-11), and *Plant Breeding* (1907; Ger. trans., 1908).

DEW. The word "dew" (OE *deaw*, cf Ger *Tau*) is a very ancient one. The *New English Dictionary* gives the moisture deposited in minute drops upon any cool surface by condensation of the vapour of the atmosphere, formed either in hot days during the day or towards night and plentiful in the early morning. If the deposit is in the form of ice it is called hoar frost. John Aitken's researches (Trans. Roy. Soc. of Edinburgh, xxii, and Nature, vol. xxxii)

suggest that the words "by condensation of the vapour in the atmosphere" might be omitted because the large dewdrops on the leaves of plants, the most characteristic of all dew phenomena, are largely an exudation of water from the plant itself through the leaf pores and are merely the continuation of the plant's irrigation process for supplying the leaves with water from the soil. The action, set up in full vigour in the daytime, is intended to maintain tolerable thermal conditions of the leaf surface in the hot sun, and continues after sunset.

Nevertheless, the typical experiment to illustrate dew formation is the production of a deposit of minute drops of moisture upon the exterior surface of a glass or polished metal vessel by the cooling of a liquid which it contains. The usual liquids are water cooled by pieces of ice, or ether, volatilized by bubbling air through it. No deposit is formed by this process until the temperature is reduced to a certain critical level which depends upon the state of the surrounding air. The physical analogy between the natural formation of dew and this artificial production is considered so complete that the critical level below which the temperature of a surface must be reduced in order to obtain the deposit is known as the "dew point."

Physicists consider the dew point to be the temperature at which, by being cooled without change of pressure, air becomes saturated with water vapour, because of a reduced capacity of the air at the lower temperature for holding water. It is a well established proposition that the pressure of the existing water vapour remains constant if the air is cooled without change of its total external pressure, hence, the saturation pressure at initial dew point gives the pressure of the water vapour. Tables of pressures of saturated water vapour for various temperatures have been compiled, thus, this mode of determining the dew point is a recognized method of measuring the pressure and amount of water vapour in the atmosphere, it is of fundamental importance in hygrometry. The physical explanation of dew formation is arrived at by determining the manner in which dew-laden objects in the open air have become cooled "below the dew point."

The whole question of radiation was first studied by Macedonio Melloni (1798-1854) and by other physicists, but little was added to the explanation given by Wells until 1880 when John Aitken showed that condensation did not take place even when the air was cooled below dew point if all nuclei for condensation had been removed, but his most important contribution on this matter was in 1885 when he called attention to the question of whether the water of dewdrops on plants or stones came from the air or the earth, either by plants exuding dewdrops, or by evaporation and subsequent condensation in the lowest layer of the atmosphere. Aitken's views at least showed that the physical processes operative in the evolution of meteorological phenomena are generally complex. The conditions favourable for the formation of dew are: (1) a good radiating surface, (2) a still atmosphere, (3) a clear sky, (4) thermal insulation of the radiating surface, (5) with moist ground or some other supply of moisture in the soil, (6) the layers of air. Aitken's main contribution showed that moisture of the ground as well as that of the air is important and that the temperature of both had to be considered. On the five

conditions, the first four are essential, but the fifth is important for securing a copious deposit.

The amount of dew deposited may be considerable, and, in tropical countries, is sometimes sufficient to be collected by gutters, but it is not generally regarded as a large percentage of the total rainfall. P. Loeschke probably overestimates a single night's dew deposition on the Loango coast at 3 mm., but measurements show that the aggregate annual deposit of dew corresponds to a depth of 1 to 1.5 in. of water near London (G. Dines), 1.2 in. at Munich (E. Wolny), 0.3 in. at Montpellier (A. Crova) and 1.6 in. at Tenbury, Worcestershire (W. F. Badgley).

The maintenance of "dew ponds" is intimately associated with this matter of total amount. Dew ponds are certain isolated ponds on the upper levels of the chalk downs of the south of England and elsewhere used as a water supply for cattle. Some of them are very ancient, as the title of a book on *Neolithic Dew ponds* (Lon'or, 1904, 1907) by A. J. and G. Hubbard indicates. Their name implies that they depend upon dew and not entirely upon rain for their maintenance. Though the question has not been settled, the balance of evidence suggests that dew deposits do not make any important contribution to the water supply. The construction of dew ponds is, however, still practised on traditional lines. Although there is some difference of opinion on the matter, it seems necessary for a new dew pond to be filled artificially first since it will not function by a natural accumulation of water in the impervious basin.

DEWAN, or **DIWAN**, an Arabic word for finance minister or financial department. In India in the 13th and 14th centuries it meant the revenue ministry, the control of which was one of the functions of the wazir, or chief minister. Akbar, in the 16th century, realizing the danger of a minister with unlimited powers, entrusted the financial administration to an official called the diwan, who was assisted by provincial diwans directly responsible to the central government. In the 17th and 18th centuries the term *diwan* was applied to the revenue administration in contradistinction to the *nizamat*, or general administration. In modern India the term *diwan* denotes the civil courts of law.

See Ibn Hasan, *The Central Structure of the Mughal Empire* (Oxford, 1936), and P. Saran, *The Provincial Government of the Mughals* (Allahabad, 1941).

DEWAR, SIR JAMES (1842-1923), British chemist and physicist, was born at Kincardine on Forth, Scot., on Sept. 20, 1842. He was very fond of music as a child, and when he met with an accident which prevented him from playing the flute, he practised making fiddles and so acquired a manual dexterity which served him in good stead in later years. He was educated at Dollar academy, Dollar, Clackmannshire, and Edinburgh university, being first a pupil, and afterward the assistant, of Lyon Playfair, then professor of chemistry; he also studied under Friedrich Kekulé (q.v.) at Ghent in 1867. In 1875 he was elected Jacksonian professor of natural experimental philosophy at Cambridge, and in 1877 he succeeded J. H. Gladstone as Fullerton professor of chemistry in the Royal institution, London. He was president of the Chemical society in 1897 and of the British association in 1902, served on the Balfour commission on London water supply (1893-94), and as a member of the committee on explosives (1888-91) invented cordite jointly with Sir Frederick Abel. He was awarded the Rumford medal of the Royal society in 1894, and the Smithsonian institution, the French Academy of Sciences, the Italian Society of Sciences and the Royal society of Arts honoured his work. He was knighted in 1904, and died on March 27, 1923.

Dewar's scientific work covers a wide field. His earlier papers deal with organic chemistry, with measurement of high temperatures, with electrophotometry and the chemistry of the electric arc. With J. G. McKendrick, of Glasgow, he investigated the physiological action of light, and examined the changes which take place in the electrical condition of the retina under its influence. The work was done mostly at night since it involved vivisection. With G. D. Livinge of Cambridge he began in 1878 a long series of spectroscopic observations inspired primarily by Sir Joseph Norman Lockyer's claims to have decomposed elements at high

temperatures. The results were published in 1915 as *Collected Papers in Spectroscopy*. With J. A. Fleming, of University college London, he investigated the specific inductive capacity of substances at very low temperatures. Dewar is best known for his work on the liquefaction of the so-called permanent gases (*the LIQUEFACTION OF GASES*), and for his researches at temperatures approaching the absolute zero. His interest in this branch of inquiry dates back at least as far as 1874, when he discussed the "Latent Heat of Liquid Gases" before the British association. Subsequently he was stimulated by the work of L. P. Caulliet and R. P. Pictet in 1877, and of Z. F. Wroblewski and K. S. Olszewski a few years later, and by 1891 Dewar had constructed a machine for producing liquid oxygen in quantity. He made use of this liquid for some low temperature experiments on meteorites, and in 1891 showed that both liquid oxygen and ozone are magnetic. He introduced the use of liquefied gases as aids in studies at very low temperatures.

About 1892 the idea occurred to him of using vacuum jacketed vessels for the storage of liquid gases, and so efficient did this device prove in preventing the influx of external heat that it was found possible to preserve the liquids for comparatively long periods, this apparatus which he designed is known as the "Dewar flask," and is invaluable for low temperature work. The principle has been used extensively in the common "thermos bottle," or vacuum flask. He next experimented with a high pressure hydrogen jet by which low temperatures were realized through the Joule-Thomson effect (*see THERMODYNAMICS*), and the successful results thus obtained led him to build at the Royal institution the large refrigerating machine by which hydrogen was first liquefied in 1898 and solidified in 1899. He investigated the gas absorbing powers of charcoal cooled to low temperatures, and applied them to the production of high vacua and to gas analysis.

With collaborators he also studied the physical and chemical properties of iron and nickel carbonyls, the properties of thin films and atomic heats at low temperatures. Dewar had a fine directing power and did excellent work with competent assistants. His greatest strength was probably in his manipulative skill, and his lectures at the Royal institution were remarkable for the experimental demonstrations, which he developed into a fine art. The chemical and physical studies are contained in *The Collected Papers*, 2 vol. (1927).

See Royal Institution lecture by H. E. Armstrong (Jan. 1924), also *Journal of the Chemical Society* (London, 1918).

DEWAR VESSEL, or **THERMOS FLASK**, a vacuum vessel invented by Sir James Dewar during his research on the liquefaction of gases (q.v.).

DEWAS, two Indian states, in the Bhopal agency of central India, founded in the first half of the 18th century by two brothers, Punwar Maharrats, who came into Malwa with the peshwa Bajji Rao in 1728. Their descendants are known as the senior and junior branches of the family, and after 1841 each ruled his own portion as a separate state, though the lands belonging to them are so intimately entangled that even in Dewas, the capital town, the two sides of the main street are under different administrations, and have different arrangements for water supply and lighting. The senior branch has an area of 449 sq mi., pop. (1941) 89,352, the area of the junior branch is 419 sq mi., pop. (1941) 83,669. The two chiefs reside in different palaces in the town of Dewas, and each is entitled to a salute of 15 guns.

DEWBERRY, or **TRAILING BLACKBERRY**, any blackberry lacking sufficiently woody fibre in the stems to stand more or less erect. In England and other countries of Europe, applied especially to *Rubus caesius*, a trailing plant, common in woods, hedges and the borders of fields. The leaves have three leaflets, are hairy beneath and of a dusky green, the flowers, which appear in June and July, are white, or pale rose-coloured. The fruit is closely embraced by the calyx and consists of a few drupelets, black with a glaucous bloom, it has an agreeable acid taste. In the eastern, southern and Pacific areas of the United States several trailing native species of *Rubus*, especially *R. flogeatus*, *R. baleyanus*, *R. hispida*, *R. ensiformis* and *R. trivialis*, produce excellent fruits, some varieties of which, as the Lucretia (prob. *R.*

general board of the navy for the last seven years of his life to the end of his life he continued to urge the building of large battleships, citing their superiority in the battle of Jutland. In 1913 he published his *Autobiography*. He died in Washington, D.C., on Jan. 16, 1917, and was buried in the Arlington National cemetery. His body was transferred March 28, 1925, to the crypt of the Bethlehem chapel of the National Episcopal cathedral in Washington.

DEWEY, JOHN (1859-1952), U.S. philosopher, psychologist and educator, was born in Burlington, Vt., on Oct. 20, 1859. He graduated from the University of Vermont, Burlington, in 1879 and from Johns Hopkins university, Baltimore Md., in 1884. Then he went west, and taught philosophy at the universities of Minnesota, Minneapolis, (1888-89), Michigan, Ann Arbor, (1889-94) and Chicago (1894-1904). It was as director of the school of education at the last institution that he first won national fame, he established an experimental school and carried out the ideas of the "new pedagogy." It was in this experience that he came to formulate principles of democratic and occupational instruction which revolutionized educational practice in the U.S., and influenced many teachers in Europe and Asia. For two years he lectured on education and philosophy at the University of Peking, and the Turkish government engaged him to draw up a report on the reorganization of its national schools.

Dewey's outlook on education reflected the industrial revolution and the development of democracy, it reacted strongly against the classical approach and authoritarian methods of aristocratic days when education consisted in learning how to talk about things rather than how to do them. The exodus from the field to the factory, the multiplication of machinery and the growing complexity of urban life required a new curriculum, teaching through practice the arts and discipline of the industrial life. This plea for practicality formed a naturally systematic whole with Dewey's "instrumental" logic, and his lifelong effort to free U.S. philosophy from its sterile preoccupation with German epistemology. In developing his thought out of the German idealism which marked the idealism of his early period—a change caused largely by the influence of William James—he retained from it an enduring sense of the value of intelligence.

The starting point of his system of thought is biological. He saw man as an organism in an environment, remarking as well as made. Things are to be understood through their origins and their functions, without the intrusion of supernatural considerations, even the Schopenhauerian *Will* and the Bergsonian *Élan vital* are mystical phrases which the philosopher will avoid. The only reality is experience, and all experience is of objects in relation. It is true that things are known only as known, but this knowledge, to be real, must be functional rather than conceptual, it must see not so much the abstract nature of the thing, as its actual operations and relations in the world of our living experience. Thought is an organ of response, it is an instrument of behaviour, rather than of knowledge in the older sense ("knowledge about"), every idea, to have meaning, must be a way of dealing specifically with actual stimuli and situations (Here Dewey anticipated "behaviourism," without falling into its exaggerations.) Thinking begins not with premises, but with difficulties, and it concludes not with a certainty but with a hypothesis that can be made "true" only by the pragmatic sanction of experiment. An idea, then, is true in proportion as it is an effective instrument in the illumination of experience and the realization of desire. Thought should aim not merely to "understand" the world, but to control and refashion it, the Spencian definition of education as the adaptation of the individual to his environment must be replaced by the practice of education as the development of all those capacities in the individual which will enable him to control his environment and fulfil his possibilities.

Further, since the individual is to live in a society, he is to be studied as a citizen (actual or potential) growing and thinking in a vast complex of interactions and relationships, not as a

solitary "self" or "soul." Through education, training and suggestion of a thousand kinds, he is made in the image of his fellows, and his thinking is largely their thinking through him. If this reduces his uniqueness, it extends the limits of his possible development far beyond those within which it was confined by the old theory of unchangeable heredity. Faith in education as the soundest instrumentality of social, political and moral reconstruction is justified by this malleability of the instincts, and this illimitableness of human growth.

Contemporary difficulties, Dewey believed, are the difficulties of a chaotic adolescence, and the disproportion between our powers and our wisdom. "Physical science," he wrote, in a passage that influenced much later thinking, "has for the time being far outrun psychical. We have mastered the physical mechanism sufficiently to turn out possible goods, we have not gained a knowledge of the conditions through which possible values become actual in life, and so are still at the mercy of habit, of haphazard, and hence of force. With tremendous increase in our control of nature, in our ability to utilize nature for human use and satisfaction, we find the actual realization of ends, the enjoyment of values, growing unassured and precarious. At times it seems as though we were caught in a contradiction, the more we multiply means the less certain and general is the use we are able to make of them." (*Influence of Darwin on Philosophy*, p. 71.)

The task of remaking man to a mental and moral level commensurate with the enlarged and intricate world in which his inventions have enveloped him lies upon democracy and education. Democracy not merely in voting but in opportunity equal to all, in education through comradesly occupation, in industry through the replacement of autocracy with voluntary association, in foreign relations through the replacement of war with conference and law. And education not in theory but in specific and experimental thinking, our social ills are to be handled no longer with majestic abstractions like individualism and socialism, competition and co-operation, dictatorship and democracy, but with restricted inquiries, specific analysis, careful formulation, patient experimentation and piecemeal renovation. We must attack the enemy as Napoleon did—in sections and detail.

The great need, then, is intelligence, and Socrates was not far wrong in counting this as the highest virtue. And again, not intellectuality, which is just the opposite of specific and realistic thought, but that flexibility of mind which can readjust past experience to novel stimuli and purposes. There is no absolute good here, no *summum bonum*, the ethical aim must vary with time and person and place, and only intelligence can specifically and transiently determine it. One thing alone seems universally good, and that is growth. "Not perfection as a final goal, but the ever enduring process of perfecting, maturing, refining, is the aim in living. The bad man is the man who, no matter how good he has been, is beginning to deteriorate, to grow less good. The good man is the man who, no matter how morally unworthy he has been, is moving to become better. Such a conception makes one severe in judging himself and humane in judging others" (*Reconstruction in Philosophy*, p. 177.)

It was not till Dewey came in 1904 to join the department of philosophy at Columbia university that his influence began to reach out from pedagogy to the philosophical and social thought of his time. He maintained this position of professor of philosophy at Columbia university until July 1, 1930, when he retired with the title of professor emeritus. In 1937 he visited Mexico as head of a commission investigating the validity of soviet charges against Leon Trotsky who had been granted political asylum in that country. He spent his remaining years in research and died in New York, N.Y., on June 1, 1952.

DEWEY, MELVIL (1851-1931), American librarian, was born at Adams Center (N.Y.) on Dec. 10, 1851. He graduated in 1874 from Amherst college, Amherst, Mass., where he became acting librarian. In 1877 he moved to Boston, Mass., there founding and editing the *Library Journal*. He was also one of the founders of the American Library association. In 1883 he became librarian of Columbia college, New York city, and there founded the school of library economy, the first institution established for the instruction of librarians.

This school, which was very successful, was re-established in Albany, N.Y., as the State Library school under his direction, from 1889 to 1906 he was director of the New York State library, from 1889 to 1900 was secretary of the University of the State of New York and from 1904 to 1906 state director of libraries, completely reorganizing the state library, which he made one of the most efficient in the U.S., and establishing the system of travelling libraries and picture collections. His "decimal system of classification" for library cataloguing, first proposed in 1876, is extensively used. Probably more than any other single individual he was responsible for the so-called development of library science in the U.S. He died Dec. 26, 1931.

DEWEY, THOMAS EDMUND (1902-), U.S. lawyer and politician, was born March 24, 1902, in Owosso, Mich. Graduated from the University of Michigan, Ann Arbor, Mich., in 1923 he received his law degree from Columbia university, New York city, in 1925, and was admitted to the New York bar the following year.

As U.S. attorney for the southern district of New York, Dewey attained national wide prominence for successful prosecutions of gangsters and criminals. Elected district attorney of New York county in 1937 he ran for governor the following year on the Republican ticket and was defeated by only 64,000 votes. Two years later he ran again for governor of New York, this time winning.

In 1944 Dewey was nominated Republican candidate for the presidency, but lost to Pres. F. D. Roosevelt, who was running for a fourth term. In 1946 Dewey was re-elected governor of New York. He was again nominated Republican candidate for the presidency in 1948. Gov. Earl Warren of California was nominated the GOP vice-presidential candidate, and in the summer and autumn campaigning it was almost universally predicted by the press and by public opinion polls that the Dewey-Warren ticket could not lose. Dewey conducted a so-called "high level" campaign, stressing national unity, while Pres. Harry S. Truman, Democratic candidate to succeed himself, campaigned largely

on the issue that the 80th congress, Republican dominated, had shown itself inimical to labour, the farmer and liberal policies in general. In the election Dewey and Warren were defeated in what was termed one of the greatest political upsets in U.S. history.

Dewey was re-elected governor of New York for a third term in 1950.

DE WINT, PETER (1784-1849), English landscape painter, of Dutch extraction, son of an English physician, was born at Stone, Staffordshire, on Jan. 21, 1784, and died in London on Jan. 30, 1849. He studied under John Raphael Smith, the engraver, and in 1809 entered the academy schools. In 1812 he became a member of the Society of Painters in Water colours, where he exhibited for many years, as well as at the academy. De Wint ranks as one of the chief English water colourists. A number of his pictures are in the Tate gallery and the Victoria and Albert museum, London.

See William Bell Scott, *Our British Landscape Painters* (1876), W. Armstrong, *Memoir of Peter de Wint* (1888).

DE WINTER, JAN WILLEM (1750-1812), Dutch admiral, was born at Kampen, and in 1762 entered the naval service at the age of 12. He distinguished himself by his zeal and courage, and at the revolution of 1787 he had reached the rank of lieutenant. The overthrow of the "patriot" party forced him to fly to France. There he threw himself into the cause of the revolution, took part under Charles Dumouriez and Charles Fichetru in the campaigns of 1792 and 1793 and was promoted to the rank of brigadier general. When Fichetru in 1795 overran the Netherlands, De Winter returned with the French army to his native country. The states general now utilized his experience as a naval officer by making him adjunct general for the reorganization of the Dutch navy. In 1796 he was appointed vice admiral and commander in chief of the fleet. He did his best to improve it and on Oct. 17, 1797, he encountered the British fleet under Adm. Adam Duncan off Camperdown. After an obstinate struggle the Dutch were defeated, and De Winter was taken prisoner. He remained in England until December, when he was liberated by exchange. His conduct at Camperdown was declared by a court-martial to have maintained nobly the honour of the Dutch flag.

From 1798 to 1802 De Winter was ambassador to the French republic, and was then again appointed commander of the fleet. He was sent with a strong squadron to the Mediterranean to repress the Tripoli pirates, and negotiated a treaty of peace with the Tripolitan government. He enjoyed the confidence of Louis Bonaparte, when king of the Netherlands, and, after the incorporation of the Netherlands in the French empire, in an equal degree of the emperor Napoleon. By the former he was created marshal and count of Huesen, and given the command of the armée d'occéan, both by sea and land. Napoleon gave him the grand cross of the Legion of Honour, appointed him inspector general of the northern coasts and in 1811 placed him at the head of the fleet he had collected at the Levant. Soon after, in 1812, De Winter became ill and moved to Paris, where he died on June 2, 1812. He was buried in the Pantheon. His heart was enclosed in an urn and placed in the Nicolaas Kerckhof Kampen.

DE WITT, CORNELIUS (1625-1671), brother of John de Witt (q.v.), was born at Dorp in 1623. In 1650 he became burgomaster of Dorp and member of the states of Holland and West Friesland. He was afterward appointed governor of the land of Putten and of Babeloerland. He associated himself closely with his brother the grand pensionary, and supported him throughout his career with great ability and vigour. In 1667 as deputy chosen by the states of Holland to accompany Adm. Michael de Ruyter in his famous expedition to Chatham Cornelius de Witt distinguished himself by his coolness and intrepidity. He again accompanied De Ruyter in 1672 and took an honourable part in the great naval night at Southwold bay against the united English and French fleets. Compelled by illness to leave the fleet, he found the Orange party on his return to Dort in the ascendant, and himself and his brother the objects of popular suspicion.

For an account of his imprisonment, trial and death see DE WITT, JOHN. (See also DUTCH WARS.)

DE WITT, JOHN (1625-1672), Dutch statesman, was born at Dort, on Sept. 4, 1625, being a member of one of the old burgher regent families of his native town. His father, Jacob, was six times burgomaster of Dort, and for many years sat for the town in the states of Holland. He was a strenuous adherent of the republican or oligarchical states right party in opposition to the princes of the house of Orange, who represented the federal principle and had the support of the masses of the people. John was educated at Leyden and early displayed remarkable talents, especially in mathematics and jurisprudence. In 1645 he and his elder brother Cornelius visited France, Italy, Switzerland and England and on his return he lived at The Hague as an advocate. In 1650 he was appointed pensionary of Dort, which made him the leader of the town's deputation in the states of Holland. In this year the states of Holland found themselves engaged in a struggle for provincial supremacy, on the question of the disbanding of troops, with the youthful prince of Orange, William III. William, with the support of the states general and the army, seized five of the leaders of the states right party and imprisoned them in Loevestein castle, among these was Jacob de Witt. The sudden death of William, at the moment when he had crushed opposition, led to a reaction. He left only a posthumous child, afterwards William III of Orange, and the principles advocated by Jacob de Witt triumphed, and the authority of the states became predominant in the republic.

It was his father's position which gave John his opportunity, but his own eloquence, wisdom and business ability which caused him to be appointed grand pensionary of Holland on July 23, 1653, at 28. He was re-elected in 1658, 1663 and 1668, and held office until just before his death in 1672. He found in 1653 his country brought to the brink of ruin through the war with England, which had been caused by the keen commercial rivalry of the two maritime states. The Dutch were unprepared and suffered severely through the loss of their carrying trade, and De Witt resolved to bring about peace. He rejected Cromwell's suggestion of the union of England and Holland, but in the autumn of 1654 peace was concluded by which the Dutch made large concessions and agreed to the striking of the flag to English ships in the narrow seas. The treaty included a secret article, which the states general refused to entertain, but which De Witt induced the states of Holland to accept, by which the provinces of Holland pledged themselves not to elect a stadtholder or a captain-general. This Act of Secclusion was aimed at the young prince of Orange, whose close relationship to the Stuarts made him an object of suspicion to the Protector. De Witt was favourable to this exclusion of William III from his ancestral dignities, but he did not prompt Cromwell.

The policy of De Witt after the peace of 1654 was eminently successful. He restored the finances of the State and extended its commercial supremacy in the East Indies. In 1658-59 he sustained Denmark against Sweden, and in 1662 concluded an advantageous peace with Portugal. The accession of Charles II to the English throne led to the rescinding of the Act of Secclusion, nevertheless De Witt steadily refused to allow the prince of Orange to be appointed stadtholder or captain general. This led to ill-will between the English and Dutch governments, and to a renewal of the old grievances about maritime and commercial rights, and war broke out in 1665. The grand pensionary himself went to sea with the fleet and inspired all by the example he set of calmness in danger, energy in action, and inflexible strength of will. It was due to his exertions as an organizer and a diplomatist quite as much as to the brilliant seamanship of Admiral de Ruyter, that the treaty of Breda (July 31, 1667), maintaining the status quo was so honourable to the United Provinces. In 1667 he promulgated his eternal edict for the republican administration of Holland. A still greater triumph of diplomatic skill was the conclusion of the Triple Alliance (Jan. 17, 1668) between the Dutch Republic, England and Sweden, which checked the attempt of Louis XIV to take possession of the Spanish Netherlands in the name of his wife, the infanta Maria Theresa.

In 1672 Louis XIV suddenly declared war and invaded the

United Provinces at the head of a splendid army. The voice of the people called William III to the head of affairs, and there were violent demonstrations against John de Witt. His brother, Cornelius, was (July 24) arrested on a charge of conspiring against the prince. On Aug. 4 John de Witt resigned the post of grand pensionary. Cornelius was put to the torture, and on Aug. 19 sentenced to deprivation of his offices and banishment. His brother came to visit him in the Gevangenpoort at The Hague. A vast crowd, hearing this, collected outside and furiously burst in, seized the two brothers and tore them to pieces. Their mingled remains were hung up by the feet to a lamp post. Thus perished, by the savage act of an infuriated mob, one of the greatest statesmen of his age, and of Dutch history.

DEWLAP, the loose fold of skin hanging from the neck of cattle, also applied to similar folds in the necks of other animals and fowls, as the dog, turkey, etc. The American practice of branding cattle by making a cut in the neck is known as a "dewlap brand." The skin of the neck in human beings often becomes pendulous with age, and is sometimes referred to humorously by the same name.

DEW-POINT see DEW

DEWSBURY, market town, county and parliamentary borough, West Riding of Yorkshire, England, on the river Calder, 8 mi. south-south-west of Leeds, on the LNE and LMS railways. Pop. (1938) 52,860. Area 9.8 sq. mi. The parish church of All Saints was for the most part rebuilt in the 18th century, the portions still preserved of the original structure are mainly Early English. The chief industries are the making of blankets, carpets, druggists and worsted yarn, and there are iron foundries and machinery works. Coal is worked in the neighbourhood. The parliamentary borough returns one member. Dewsbury was incorporated in 1862 and was created a county borough in 1913. Edwin, king of Northumbria, had a mansion here in the 7th century. At Kirkstall may be seen the remains of a Cistercian convent (12th century), in an extensive park, where tradition relates that Robin Hood died and was buried.

DEXIPPUS, PUBLIUS HERENNIUS (c. A.D. 210-273), Greek historian, statesman and general, was an hereditary priest of the Eleusinian family of the Kerykes, and held the offices of archon basileus and eponymus in Athens. When the Heruli overran Greece (269), Dexippus was made general and defeated them heavily. A statue was set up in his honour, the base of which, with an inscription recording his services, has been preserved (*Corpus Inscr. Atticarum*, III No. 716). It is remarkable that the inscription is silent as to his military achievements. Photius (cod. 82) mentions three historical works by Dexippus, of which considerable fragments remain: (1) *Tà per' Allēgandron*, an epitome of a similarly named work by Arrian; (2) *Συμβεβή*, a history of the wars of Rome with the Goths (or Scythians) in the 3rd century; (3) *Χρονική ιστορία*, a chronological history from the earliest times to the emperor Claudius Gothicus (270), frequently referred to by the writers of the Augustan history. The work was continued by Eupapius of Sardis down to 404. Photius places Dexippus on a level with Thucydides, an opinion by no means confirmed by the fragments (C. W. Muller, *F.H.G.* III 666-687).

DEXTER, HENRY MARTYN (1821-1890), U.S. clergyman and author, was born in Plympton (Mass.), on Aug. 13, 1821. A graduate of Yale and Andover theological seminary, he was pastor of Congregational Churches in Manchester (N.H.), and Boston, and edited various magazines, including the *Congregational Quarterly* and *Congregationalist*. He died in New Bedford (Mass.), on Nov. 13, 1890. He was an authority on the history of Congregationalism and was a lecturer on that subject.

at the Andover theological seminary in 1877-79. Dexter left his fine library on the Puritans in America to Yale university. Among his works are *At to Roger Williams and His "Banishment" from the Massachusetts Colony* (1876), *The Congregationalism of the Last Three Hundred Years, as Seen in Its Literature* (1880), his most important work, *Common Sense as to Woman Suffrage* (1885), and many reprints of colonial pamphlets. His *The England and Holland of the Pilgrims* (1905) was completed by his son, Morton Dexter.

See American Antiquarian Society, *Proc.* (April 1891)

DEXTRIN or **DEXTRENE** is a term applied to commercial products prepared by heating dry starch for 3 to 4 hours at 135° to 185° C., usually in the presence of traces of acid catalyst or (more rarely) an oxidizing agent. Depending on conditions of manufacture, the products range from white to tan or yellow in colour, show moderate to high solubility in water, and yield pastes or solutions of low viscosity. Principal types include white dextrans (by mild heating with hydrochloric acid), yellow and canary dextrans (stronger heating with acid), and "British gums" (strong heating without acid). Products are chiefly used as adhesives and as sizing agents for textiles and paper.

The term also applies to certain noncommercial acidic or enzymic degradation products from starch, including the crystalline Schardinger dextrans by conversion with the amylase of *B. macerans*, residual or limit dextrans produced by liquefying or saccharifying enzymes, and oligosaccharides resulting from extensive acid hydrolysis. (T. J. Sht.)

DEY, an honorary title formerly bestowed by the Turks on elderly men, and appropriated by the janissaries as the designation of their commanding officers (an adaptation of the Turk *dai*, a maternal uncle). In the 17th century the deys of the janissaries in Algiers became the rulers of that country (see *ALGERIA History*). From the middle of the 16th century to the end of the 17th century the ruler of Tunisia was also called dey, a title frequently used during the same period by the sovereigns of Tripoli.

DHAMMAPĀLA, the name of one of the early disciples of the Buddha, and therefore constantly chosen as their name in religion by Buddhist novices on their entering the brotherhood. The most famous of the Bhikkhus so named, probably a Tamil, was the great commentator who lived in the latter half of the 5th century A.D. To him we owe the commentaries on seven of the shorter canonical books, consisting almost entirely of verses, and also the commentary on the Nettis, perhaps the oldest Pāli work outside the canon. Dhammapāla confines himself rigidly to questions of the meaning of words, and to discussions of the ethical import of his texts. Other unpublished works, besides those mentioned above, have been ascribed to Dhammapāla.

BIBLIOGRAPHY—T. Watters, *On Yuan Chwang* (ed. Rhys Davids and Bushell, London, 1907), i. 169, 228; Edmund Hardy in *Zeitschrift der deutschen morgenländischen Gesellschaft* (1898), pp. 97 foll.; Nettis (ed. E. Hardy, London, Pāli Text Society, 1902), especially the Introduction, *passim*; *Theri Gāthā Commentary*, *Peta Vatthū Commentary*, and *Vimāsa Vatthū Commentary*, all three published by the Pāli Text Society.

DHANIS, FRANCIS, BARON (1861-1909), Belgian administrator, born in London and educated at the Belgian Ecole Militaire, went out to the Congo in 1887, and in 1892-94 commanded an expedition against the slave dealers. He captured 110,000 slaves and three Arab strongholds at N'ganga, K'vongo and K'hambari. He was raised to the rank of baron, and in 1895 was made vice-governor of the Congo State. In 1896 he took command of an expedition to the Upper Nile. His troops, largely composed of the Batele tribes who had only been recently enlisted, and who had been irritated by the execution of some of their chiefs for cannibalism, murdered and murdered many of their white officers. During 1897-98 he was engaged in a life-and-death struggle with them, eventually he succeeded in breaking up the bands of mutinous soldiers. In 1899 Baron Dhanis returned to Belgium. He died on Nov. 14, 1909.

See Sidney Hays, *The Fall of the Congo Kings* (1897)

DEANUSHERKODI, a seaport of Madras India, on the north end of Ramanaikan, at the junction of Tark straits and the Gulf of Manar. The port was brought into being in 1913, when the new

direct route of the South Indian railway to Ceylon was opened. The line is carried by an embankment and a bridge to Dhanushkodi, whence steamers run to Talai Manar (22 miles). Coffee, fish, rice, rubber, tea and cotton goods are exported, but no great influx of trade followed the foundation of the port. The population consists largely of railway employees.

DHAR, an Indian state in the Malwa agency, Central India. It includes many Rajput and Bhil feudatories, and has an area of 1,798 sq. mi. The raja is a Ponorwar Maharaja. The founder of the present ruling family was Anand Rao Ponwai, a descendant of the great Paramara clan of Rajputs who from the 9th to the 13th century, when they were driven out by the Mohammedans, had ruled over Malwa from their capital at Dhar. In 1742 Anand Rao received Dhar as a fief from Bajirao, the peshwa, the victory of the Marathas thus restoring the sovereign power to the family which seven centuries before had been expelled from this very city and country. Towards the close of the 18th and in the early part of the 19th century, the state was subject to a series of spoliations by Sindhi and Holkar, and was only preserved from destruction by the talents and courage of Anand Rao's widow. By a treaty of 1819 Dhar passed under British protection. The State was confiscated for rebellion in 1857, but in 1860 was restored, with the exception of the detached district of Barausa which was granted to the begum of Bhopal. The chief has the style of Maharaja and a salute of 15 guns. In 1941 the population was 253,210. The state includes the ruins of Mandu, or Mandoghar, the Mohammedan capital of Malwa.

The **TOWN OF DHAR** (pop. [1931] 19,607), is picturesquely situated among lakes and trees surrounded by barren hills, and possesses, besides its old walls, many interesting buildings, Hindu and Mohammedan, some of them containing records of great historical importance. The Lat Masjid, or Pillar Mosque, was built by Dilawar Khan in 1405 out of the remains of Jain temples. It derives its name from an iron pillar, supposed to have been originally set up at the beginning of the 13th century in commemoration of a victory, and bearing a later inscription recording the seven days' visit to the town of the emperor Akbar in 1598. The pillar, which was 43 ft. high, is now overthrown and broken. The Kamal Mula is an enclosure containing four tombs, the most notable being that of Shaikh Kamal Maulvi (Kamal-ud-din), a follower of the famous 13th-century saint Nizam-ud-din Auliya. The mosque known as Raja Bhoj's school was built out of Hindu remains in the 14th or 15th century. Its name is derived from the slabs, covered with inscriptions giving rules of Sanskrit grammar, with which it is paved. On a small hill to the north of the town stands the fort, a conspicuous pile of red sandstone, said to have been built by Mohammed ben Tughlak of Delhi in the 14th century. It contains the palace of the raja.

The town is of great antiquity, and was made the capital of the Paramara chiefs of Malwa by Varmasimha II, who transferred his headquarters thither from Ujjain at the close of the 9th century. During the rule of the Paramara dynasty Dhar was famous throughout India as a centre of culture and learning, but, after suffering various vicissitudes, it was finally conquered by the Mohammedans at the beginning of the 13th century. Subsequently, in the time of Akbar, Dhar fell under the dominion of the Moguls, in whose hands it remained till 1730, when it was conquered by the Marathas.

DHARAMPUR, native state, India, in the Surat political agency division of Bombay. Area 719 sq. mi. Pop. (1941) 123,326. Tributary, with Barot and Such 6,300. The chief is a Sesodi Rajput. The state contains one town Dharampur (pop. in 1941, 8,182). Only a small part of the state, the climate of which is very unhealthy, is cultivated. Rice, muller, pulse, etc., are grown and there are extensive forests.

DHARMSALA, a hill station and sanatorium of the Punjab, India, situated on a spur of the Dhaul Dhar, 16 mi. north-east of Kangra town, at an elevation of some 6,500 ft. Pop. (1941) 9,653. The spur is thickly wooded with oak and deodar trees, behind it the pine-clad slopes of the mountain rise towards the jagged peaks of the higher range, snow-clad for half the year, while below stretches the luxuriant cultivation of the Kangra valley.

In 1855 Dharmasala was made the headquarters of the Kangra district of the Punjab in place of Kangra, and became the centre of a European settlement and cantonment, largely occupied by Gurkha regiments. The station was destroyed by earthquake in 1905.

DHARWAR, town and district, British India, in the south ern division of Bombay. The town (pop in 1941, 47,992) is a railway centre, formerly headquarters of the Southern Mahratta railway, now amalgamated with the Madras railway. It contains a jail for juvenile criminals, a mental hospital, a college and two training colleges, and is a centre of the Basle mission.

The district of Dharwar has an area of 4,576 sq miles. In the north and north east are plains of black soil, favourable to cotton-growing, in the south and west are ranges of low hills, with flat fertile valleys between them. The whole district has high and has no large rivers. In 1941 the population was 1,202,016. The principal products are millets, pulse, cotton and timber. The centres of the cotton trade are Hubli and Gadag, junctions on the Madras and Southern Mahratta railway, which traverses the district in several directions.

The early history of the territory comprised within the district of Dharwar has been to a certain extent reconstructed from the inscription slabs and memorial stones which abound there. From these it is clear that the country fell in turn under the sway of the various dynasties that ruled in the Deccan, memorials of the Chalukyan dynasty, whether temples or inscriptions, being especially abundant. In the 14th century the district was first overrun by the Mohammedans, after which it was annexed to the newly established Hindu kingdom of Vijayanagar, an official of which named Dhar Rao, according to local tradition building the fort at Dharwar town in 1403. After the defeat of the king of Vijayanagar at Talikot (1565), Dharwar was for a few years practically independent under its Hindu governor, but in 1573 the fort was captured by the sultan of Bijapur, and Dharwar was annexed to his dominions. In 1864 the fort was taken by the emperor Aurangzeb, and Dharwar, on the break-up of the Mogul empire, fell under the sway of the peshwa of Poona. In 1764 the province was overrun by Hyder Ali of Mysore, who in 1778 captured the fort of Dharwar. This was retaken in 1791 by the Mahrattas. On the final overthrow of the peshwa in 1817 Dharwar was incorporated with the territory of the East India company.

DHOLE, the "Red Dog" of Asia, *Cuon javanicus*, distinguished from the true dogs (*Canis*) by one molar less in the lower jaw. A rufous brown in colour, the dhole is larger than a jackal and hunts in large packs. It is reported to kill animals as large as the buffalo, but deer are most hunted. *Cuon* is found from India north to Siberia and east to Sumatra and Java.

DHOLPUR, an Indian state in the Eastern Rajputana states agency, with an area of 1,173 sq mi. All along the bank of the river Chambal the country is deeply intersected by ravines, low ranges of hills in the western portion of the state supply inexhaustible quarries of fine grained and easily-worked red sandstone. In 1941 the population of Dholpur was 286,901.

The town of Dholpur is 34 mi S of Agra by rail. Pop (1931) 19,586. The present town, which dates from the 16th century, stands somewhat to the north of the site of the older Hindu town built, it is supposed in the 11th century by the Tonwar Rajput Raja Dholan (or Dhawal) Deo, and named after him. Dholera or Dhawalpur. Among the objects of interest in the town may be mentioned the fortified *sarai* built in the reign of Akbar, within which is the first tomb of Sadik Mohammed Khan (d. 1595), one of his generals.

Local tradition affirms that Dholpur was ruled by the Tonwar Rajputs, who had their seat at Delhi from the 8th to the 12th century. In 1527, after a strenuous resistance, the fort was captured by Baber and with the surrounding country passed under the sway of the Moguls, being included by Akbar in the province of Agra. During the dissensions which followed the death of Aurangzeb in 1707, Raja Kalyan Singh Bhadsama obtained possession of Dholpur, and his family retained it till 1761, after which it was taken successively by the Jat raja, Suraj Mal of Bharatpur, by Mirza Najaf Khan in 1775, by Sindia in 1782,

and in 1803 by the British. It was restored to Sindia by the Treaty of Saraj Anjanagion, but in consequence of new arrangements was again occupied by the British.

The maharaja rana of Dholpur belongs to the clan of Bamraolia Jats. A sixteenth century ancestor, Singhan Deo, having distinguished himself in an expedition against the freebooters of the Deccan, was rewarded by the sovereignty of the small territory of Gohad, with the title of *rana*. In 1779 the rana of Gohad joined the British forces against Sindia, under a treaty which stipulated that, at the conclusion of peace between the English and Mah rattas, all the territories then in his possession should be guaranteed to him, and protected from invasion by Sindia. This protection was subsequently withdrawn, the rana having been guilty of treachery, and in 1783 Sindia crushed his Jat opponent and seized the whole of Gohad. In 1804, however, the family were restored to Gohad by the British government, but, owing to the opposition of Sindia, the rana agreed in 1805 to exchange Gohad for his present territory of Dholpur, which was taken under British protection. The ruler has a salute of 15 guns. Kirat Singh, the first maharaja rana of Dholpur, as succeeded in 1836 by his son Bhagwant Singh, who showed great loyalty during the Mutiny of 1857, and was created a K.C.S.I. and G.C.S.I. in 1869. He was succeeded in 1873 by his grandson Nehal Singh, who received the C.B. and frontier medal for services in the Tirah campaign. He died in 1901 and was succeeded by his eldest son, Ram Singh. His Highness Lt.-Col. Sir Rais ud-Daula, Jai Deo, K.C.S.I., K.C.V.O., the present ruler, is the second son of the maharaja rana Nehal Singh and was born on Feb. 12, 1893. On the death of his brother maharaja rana Ram Singh, his Highness succeeded to the gadi in March 1911 and was invested with full ruling powers on Oct. 9, 1913. He has a personal salute of 17 guns.

DHOW, a type of vessel used throughout the Arabian Sea. The language to which the word belongs is unknown. Used of any craft along the East African coast, it is usually applied to the vessel of about 150 to 200 tons burden with a stem rising with a long slope from the water, dhows generally have one mast with a lateen sail, the yard being of enormous length. Much of the coasting trade of the Red Sea and Persian Gulf is carried on by these vessels. They were the regular vessels employed in the slave trade from the east coast of Africa.

DHRANGADHRA, native state, India, in the Western Indian States Agency, situated in the north of the peninsula of Kathiawar, Bombay. Area is 1,167 sq mi. Pop (1941) 94,417. Tribute, to the British government and Tunagadh, £3,000. There is a state railway (metre gauge) from Wadhwan through the town of Dhrangadhra to Halvad, a distance of 40 mi, and a short line to the state salt works was opened in 1923. The chief town, Dhrangadhra, has a population (1941) of 21,267.

The chief of Dhrangadhra, who bears the title of Raj Sahb, with the predicate of His Highness, is head of the ancient clan of Jhala Rajputs, who are said to have entered Kathiawar from Sind in the 8th century. The Raj Sahb who succeeded in 1869 was distinguished for the enlightened character of his administration, and the state continues to make progress under its present ruler, who succeeded in 1911. It came into direct relations with the British Government in 1914.

DHULEEP SINGH (1837-1893), maharaja of Lahore, was born in Feb. 1837, and was proclaimed maharaja on Sept. 18, 1843, under the regency of his mother the rani Jindan, a woman of great capacity and strong will, but extremely inimical to the British. He was acknowledged by Ranjit Singh and recognized by the British Government. After six years of peace the Sikhs invaded British territory in 1845, but were defeated in four battles, and terms were imposed upon them at Lahore, the capital of the Punjab. Dhuleep Singh retained his territory, but it was administered to a great extent by the British Government in his name. This arrangement increased the regent's dislike of the British, and a fresh outbreak occurred in 1848-49. The Sikhs were routed at Gujarat, and in March 1849 Dhuleep Singh was deposed, a pension of £40,000 a year being granted to him and his dependents. He became a Christian and elected to live in England. On coming of age he made an arrangement with the British

government by which his income was reduced to £25,000 in consideration of advances for the purchase of an estate, and he finally settled at Elveden in Suffolk. In 1864 he married Bamba Müller, a German missionary worker in Egypt, by whom he had six children. After her death he married in 1890 an Englishwoman, Adä Wüthenill. The maharaja was passionately fond of sport, and his shooting parties were celebrated, while he himself became a *petitona grata* in English society. The result, however, was financial difficulty and in 1882 he appealed to the government for assistance, making various claims based upon the alleged possession of private estates in the Punjab, and upon the surrender of the Koh-i-noor diamond to the British crown. His demand was rejected, whereupon he started for India, after drawing up a proclamation to his former subjects. But as it was deemed inadvisable to allow him to visit the Punjab, he remained for some time as a guest at the residency at Aden, and was allowed to receive some of his relatives to witness his abjuration of Christianity, which actually took place within the residency itself. As the climate began to affect his health, the maharaja at length left Aden, and returned to Europe. He stayed for some time in Russia hoping that his claim against England would be taken up by the Russians, but when that expectation proved futile he proceeded to Paris, where he lived for the rest of his life on the pension allowed him by the Indian government. His death from an attack of apoplexy took place at Paris on Oct. 22, 1893.

The maharaja's eldest son, Prince Victor Albert Jay Dhuleep Singh (1866-1918), was educated at Trinity and Downing colleges, Cambridge. In 1888 he obtained a commission in the 1st Royal Dragoon Guards. In 1898 he married Lady Anne Coventry, youngest daughter of the earl of Coventry. He died without issue on June 7, 1918.

DHULIA, town, British India, administrative headquarters of the West Khandesh district in Bombay, on the right bank of the Panjra river. Pop. (1941) 53,368. Considerable trade is done in cotton and oil seeds; cotton and wool are woven, cotton ginning and pressing carried on. There is a technical school. A railway connects Dhulia with Chalisgaon, on the main Great Indian Peninsula railway.

DIABASE (US usage) is a medium- to fine grained rock which occurs in sills or dikes, has the mineral composition of basalt and usually has an ophitic texture. Neither age nor condition of preservation is considered in this definition. The rock is in reality an intrusive basalt, and it is only the different mode of occurrence that gives to it its different texture. As a matter of fact, a thick flow of basalt may have the same ophitic texture, and the two rocks may appear alike in thin sections. While the essential minerals are augite and labradorite, and a common accessory is magnetite, other minerals may be present as accessories or proves, and if unusual or abundant are mentioned in the name. Thus, we have olivine diabase, hypersthene-diabase, quartz bearing diabase, etc.

Historically, certain rocks, thought to be composed essentially of amphibole, chlorite and feldspar, were called *Grunstone* by Abraham G. Werner and Carl Haidinger in 1787. Alexander Brongniart, in 1807, substituted the term diabase (*diabasis*, "a crossing over"), but in 1827 withdrew it in favour of diorite. The discarded term was revived in 1842 by J. F. L. Hausmann after Gustav Rose had shown that most of the *Grunsteine* carried pyroxene and not amphibole, and that the feldspar was labradorite or andesine.

F. Zirkel, in 1866 limited the term diabase to rocks composed of pyroxene and labradorite, usually with secondary chlorite or coarse to fine texture and occurring in sheets or dikes. Herr Rosenbusch in 1877 gave essentially the same composition but introduced the age factor and defined diabases as pre-Tertiary rocks, later he said they might extend from early Pliocene to recent times. The texture he defined as intersertal porphyritic (ophitic). English usage is to give the name dolerite to rocks which in the U.S. are called diabase. While Alfred Harker in 1902 used the term diabase with its essential meaning as that current in the U.S., in 1908 he substituted the word dolerite in the definition, which otherwise was unchanged.

Arthur Holmes in 1920 gave the modern British usage when he defined diabase as an altered dolerite in which the feldspars are saussuritized or albitized, or the pyroxene more or less replaced by hornblende or chlorite. (A. Jo.)

DIABELLI, ANTON ANTONIO (1781-1858), composer of pianoforte and church music, was born on Sept. 6, 1781, at Mattsee near Salzburg, Austria. He was educated in the convent of Rarchenhaslach, it being intended that he should become a priest. He abandoned the idea of taking orders, however, on the secularization of the Bavarian convents in 1803. Diabelli went to Vienna where his piano pieces and arrangements became extremely popular. His other compositions included songs and an opera, *Adam in der Klemme*, while his masses, particularly the *Lendmesser*, are widely known in Austria.

With the aid of money he earned as a teacher of the guitar and pianoforte, he was able to become a partner of Peter Cappi, the music publisher, in 1818. Six years later the firm became known as Diabelli and Co., which published for Schubert, Czerny, Strauss, Lanner, and others. On a waltz of Diabelli's, Beethoven wrote his 33 Variations (Op. 120).

DIABETES INSIPIDUS is a disease characterized by the excretion of large volumes of urine of a low specific gravity accompanied by an abnormally great thirst which is probably secondary to the polyuria. It is caused by destruction of the neural lobe of the pituitary gland or by lesions in the supra optical-hypophyseal tracts, the nervous connections between the hypothalamus and the neural lobe. The condition can be alleviated but not cured by the administration of posterior pituitary extract. (F. L. A.)

DIABETES MELLITUS is a condition in which the body is unable to metabolize sugars and other food materials efficiently. It is this disease which is commonly termed "diabetes" (see METABOLIC DISEASES) and it is believed to be produced when there is insufficient available insulin (*qv*) in the body. The first suggestion that the pancreas (*qv*) is necessary for the complete utilization of carbohydrates in the animal body was made by Johann Conrad von Brunner in 1682. The relationship of the pancreas to diabetes was first suggested in 1788 by Cawley, an English physician. In 1889 J. von Mering and O. Minkowski showed that the complete removal of the pancreas from dogs resulted in a condition which is practically identical with diabetes mellitus in man. Although attempts were made by scores of investigators to secure an antidiabetic substance from the pancreas, this substance, called insulin, was not proved to be present until 1921 (see INSULIN). In some cases the diabetic condition may be the direct result of a decrease in the formation and secretion of insulin by the pancreas, while in others the defect may be primarily the result of an altered activity of other glands.

Diabetes is a common disease. There are clear references to it in the ancient literature of Egypt, China and India. At mid century the results of pilot surveys indicated that there are about 1,000,000 known diabetics in the United States and an equal number as yet undetected. No age is exempt, but most patients are over 40 at the onset of the disease. Obese persons more often suffer from diabetes than those of normal weight. There are more male than female diabetics.

Signs and Symptoms—The untreated diabetic patient suffers from extreme thirst, hunger, loss of weight and strength. He excretes abnormally large quantities of urine of high specific gravity (1.030 to 1.050) containing sugar and other substances not usually present. He is very susceptible to infection, and the infection when established is difficult to eliminate.

The diabetic condition is suspected when a patient complains of one or more of these signs or symptoms. A person may be a mild diabetic for a long time before he is aware of his condition. Diabetes as a rule advances comparatively slowly except in the young, in whom its progress is often rapid. Occasionally in children the disease progresses so rapidly that the patient develops in acidosis, often vomits, and may lapse into coma within a few days of what is apparently an acute onset of the disease. The routine analysis of the urine in life-insurance examinations and of those entering the armed forces has resulted in the early diag-

nosis of many cases of unsuspected diabetes. The prognosis of the early case is, of course much better than that of the advanced since treatment can be instituted earlier in the disease. The amount of sugar in the blood under certain standard conditions is a valuable indication of the severity of the disease. The presence in the urine of the acetone bodies resulting from the excessive breakdown of fats is a warning that acidosis and coma are imminent. The presence of these substances in the body can sometimes be suspected from the odour which one of them, acetone, imparts to the breath.

The most characteristic finding is that of sugar in the urine, though it alone is not diagnostic of the diabetic condition. The amount of sugar thus excreted may be small or very great, depending upon the severity of the disease and upon the amount of sugar or starchy food eaten by the patient. Because the diabetic person does not use sugar as readily as a normal person sugar accumulates in the blood and is excreted in the urine. The metabolism of fats is increased to such an extent that the intermediary products, called acetone bodies, are not completely oxidized as in the normal person, and these substances also accumulate in the blood and are excreted in the urine. Two of these acetone bodies are acids and are excreted in combination with alkali, which is thus removed from the body, and so there develops a condition of acidosis that may lead to coma.

The complications of the inadequately treated disease are many and serious. Vision may become impaired. Skin infections of all kinds may occur and prove very intractable. Boils, carbuncles, cellulites and gangrene are all apt to occur as life advances. There is especial danger of gangrene of the toes and feet. Diabetics are especially liable to tuberculous. Digestive troubles, kidney diseases and diseases of the heart and particularly arteriosclerosis are of common occurrence. But the most serious complication of all is diabetic coma. The onset of this condition is often insidious, but may be indicated by loss of appetite, a rapid fall in the quantity both of urine and of sugar in the urine, and by either constipation or diarrhoea. At first the condition is rather that of collapse than of true coma, though later the patient is completely comatose. He suffers from a peculiar kind of dyspnoea (difficult breathing) and the breath and skin have a sweet ethereal odour. The condition may last from one to three days, only very rarely longer, and was almost invariably the precursor of death in preinsulin days.

Treatment—Patients suffering from diabetes mellitus are treated by dietetic measures, and if the condition is of moderate or severe intensity, by the administration of insulin. Before the discovery of insulin the methods of treatment introduced by Frederick Madison Allen and by Elliott P. Joslin, of drastic restrictions in diet, prolonged the lives of many severe diabetics.

Several important principles underlie the dietetic treatment of this disease. The diet must supply sufficient calories to keep the patient's weight constant at the proper level. Protein, preferably as lean meat, eggs and milk, must not be reduced below a certain minimum value. If proteins are unduly reduced, the tissue proteins of the patient's body are drawn upon. Some diabetics are recommended a diet rich in fat substances, while others are given a diet high in starchy foods. Excess of sugar is excreted in the urine, and the amount of sugar so excreted can readily be determined by chemical analysis. Tables are available showing what substitutions may be made in the diet without changing the sugar available to the body.

The diabetic diet should consist as far as possible of easily available seasonable foods along the line of a normal diet. It is much more satisfactory for the patient to obtain the essentials of his diet from among these common foods than to be largely dependent upon specially prepared diabetic foods. The diabetic diet need not be monotonous.

Insulin, which is distributed as a sterile, slightly acid solution, is injected hypodermically. There is no substitute for insulin. The amount necessary depends upon the severity of the disease, upon the quantity and nature of the diet, and upon the activity of the individual. In general, enough insulin is given to reduce the high concentration of sugar in the blood of the diabetic to the

level of that of a normal person. It is given every day, usually before breakfast, and sometimes again later in the day.

If the diet is unbalanced with respect to the relative amounts of proteins, fats and carbohydrates, or if there is a serious lack of insulin a diabetic may pass into coma. The treatment of coma before insulin was available was to put the patient to bed, supply fluids, heat and stimulants, and give sugar by mouth or by vein. These general measures are in large part still necessary. Insulin has proved a specific remedy in the treatment of this condition, and when it is given early enough and in large doses, the results have been very successful.

A very serious condition may be produced by an overdose of insulin. A low concentration of sugar in the blood (hypoglycaemia) will result. It may be avoided on the physician's part by a careful balancing of diet against dosage of insulin, and on the patient's part by a close and intelligent observance of the diet, together with a thorough understanding of the premonitory symptoms of the beginning of a hypoglycaemic reaction. The symptoms of slight hypoglycaemia are sudden hunger, fatigue, a peculiar restlessness often described by the patient as a feeling of 'inward trembling,' pallor or flushing of the face and an increased pulse rate, a particularly valuable sign in children. If the overdose of insulin is large, and corrective measures are not taken, the patient may show profuse perspiration, tremor, emotional disturbances, collapse and unconsciousness. The treatment of mild or moderate degrees of hypoglycaemia consists of the administration of carbohydrate in any convenient form such as ordinary sugar or candy or diluted corn syrup. In severe cases a sterile solution of dextrose is given intravenously by a physician.

Prognosis—Before the use of insulin fewer than 20% of patients suffering from severe diabetes lived more than ten years. Children, who usually have the disease in a severe form, seldom lived for more than a year. With the increasing knowledge of the disease and its treatment, it was estimated, 25 years after the discovery of insulin, that the life expectancy of a diabetic child was only ten years less than that of a healthy nondiabetic child. Diabetic women on a careful dietary regime, receiving insulin and other necessary treatment, can now bear healthy babies. Most persons who have diabetes can keep well and lead successful and useful lives, but constant and intelligent attention to the details of treatment by both patient and physician are necessary.

DIABOLO, a game played with a sort of top, in the shape of two cones joined at their apexes, which is spun, thrown and caught by means of a cord strung to two sticks. The idea of the game appears originally to have come from China, where a top (*Koungen*), made of two hollow pierced cylinders of metal or wood joined by a rod, often of immense size, was made by rotation to hum with a loud noise, and was used by pedlars to attract customers. From China it was introduced by missionaries to Europe, a form of the game, known as "the devil on two sticks," appears to have been known in England toward the end of the 18th century.

At intervals occasional attempts were made to revive the game of spinning a top of this sort on a string, but it was not till 1906 that the sensation of 1812 began to be repeated. A French engineer, Gustave Philippart, discovering some old implements of the game, had experimented for some time with new forms of top with a view to bringing it again into popularity, having devised the double-cone shape, and added a miniature bicycle tire of rubber round the rims of the two ends of the double cone, with other improvements, he named it "diabolo." The use of celluloid in preference to metal or wood as its material appears to have been the result of a suggestion of C. B. Fry, who was consulted by the inventor on the subject.

The game of spinning, throwing and catching the diabolo was rapidly elaborated thereafter.

DIACONICON, in the Greek Church, the name given to a chamber on the south side of the central apse, where the sacred utensils, vessels, etc. of the church were kept. In the reign of Justin II (565-574), owing to a change in the liturgy, the diaconicon was located in an apse at the east end of the south aisle, a similar apse at the east end of the north aisle was used as the prothesis (*q v*)—the place where the elements of the Communion were prepared. In the churches in central Syria, of slightly earlier date, there is only one apse and the diaconicon is rectangular (T F H)

DIADOCHI, *s s*, "Successor" (Gr *διαδοχισταί*), the name given to the Macedonian generals who fought for the empire of Alexander after his death in 323 B C. The name includes Antigonus and his son Demetrius Poliorcetes, Antipater and his son Cassander, Seleucus, Ptolemy, Eumenes and Lysimachus. The kingdoms into which the Macedonian empire were divided under these rulers are known as Hellenistic. The chief were Asia Minor and Syria under the Seleucid dynasty (*q v*), Egypt under the Ptolemies (*q v*), Macedonia under the successors of Antigonus Gonatas, Pergamum (*q v*) under the Attalid dynasty. Gradually these kingdoms were merged in the Roman empire (See MACEDONIAN EMPIRE) (X)

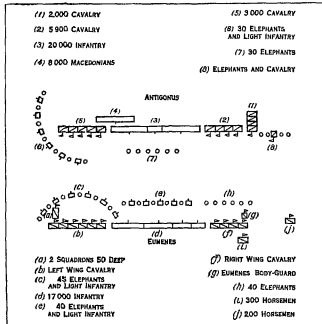

DIADOCHI, WARS OF (323-281 B C) The wars of the Diadochi, or Successors, though outwardly civil wars ending in the disruption of the Alexandrine empire, were inwardly the birth pangs of a new civilization begotten by Persian gold set into circulation through strife. Few periods in history have produced so many great generals, the reason being that the chief participants in these wars, namely, Antipater, Craterus, Perdicas, Ptolemy, Lysimachus, Seleucus and Eumenes had all been selected by Alexander and trained in his campaigns.

To the Death of Perdicas, 321 B C—Alexander died in June 323, but before the year was out civil war was raging throughout Greece. This conflagration was known as the Lamian war, and to quell it Antipater sent for Craterus then in Cilicia on his way back to Greece with Alexander's discharged veterans. On his arrival he met the Grecian allied forces on the plains of Crannon and routed them. Free of this menace, Antipater and Craterus, fearing the growing power of Perdicas, entered into a league with Ptolemy, who was nervous lest Perdicas should attempt to dispossess him of Egypt. Nor were his fears unfounded, for in the spring of 321 Perdicas, accompanied by Philip Arrhineus, the weak-minded half-brother of Alexander, marched against Egypt, whereupon Craterus and Neoptolemus invaded Asia, both being killed in a battle with Eumenes. Perdicas did not, however, live to hear of this victory, for on the Pelusiac branch of the Nile his men mutinied and assassinated him. The battle fought by Eumenes is mainly of strategical interest, since Perdicas and Eumenes held a central position and were threatened by Antipater from the west and by Ptolemy from the south. Antipater's plan was first to smash Eumenes and hold off Perdicas, secondly to concentrate against the latter. Perdicas attempted to counter this plan by sending Eumenes to hold back Antipater's two generals whilst he fell upon Ptolemy. Both coalitions aimed at destroying each other in detail, the one working on interior lines and the other on exterior. From the very outset of this war we find strategy dominating tactics, the reason being that all the generals concerned are men of high military ability.

To the Death of Eumenes, 316 B C—By the death of Perdicas the preponderance of power was thrown into the hands of Antipater, Ptolemy and Antigonus. As Antipater had just uttered a reverse, Antigonus, seeing Eumenes without an ally, marched against him. Eumenes, robbed of the fruits of his victory, was faced by a numerous army. Putting to death the invaders he turned to meet Antigonus, whereupon his cavalry under Apollonides deserted to the enemy. This compelled Eumenes to seek refuge in the fortress of Nora, which was at once besieged by Antigonus. Meanwhile Antipater died, but shortly before his death he set aside his son Cassander and appointed as his successor Polyperchon. Antigonus, hearing of the differences between these two, saw a chance of increasing his dominion, and to the quest of the siege he proposed favourable terms to Eumenes, who was at

once bought over by Polyperchon, who sent to him the Argyraspides (Silver Shields), a formidable body of Alexander's veterans. A series of manoeuvres now took place, the two antagonists coming into contact in Media. Eumenes had 35,000 foot, 6,100 horse, and 114 elephants, and Antigonus 82,000 foot, 8,500 horse and 65 elephants. The orders of battle of the two armies are given in the diagram.

The tactics of this battle are interesting. Antigonus, seeing that Eumenes had deployed his best horsemen on his right, drew up

PLAN OF THE FIRST BATTLE BETWEEN EUMENES AND ANTIGONUS

1,000 horse archers and 1,000 lancers in columns of squadrons so that they could "charge in manner of a running fight, wheeling off one after another, and so still renew the fight by fresh men." He did this to hold his enemy's main attack. Eumenes, to protect his left wing, drew up his elephants in a demi lune, from which it may be inferred that this wing was to be refused. Antigonus in order to protect his right wing, which was to deliver the main attack, extended his elephants in a semi-circle on its outer flank.

Antigonus advanced with his right leading, but not being able to encounter the elephants he wheeled outwards and poured showers of arrows on to his enemy's left flank. Eumenes, withdrawing a force of cavalry from his right, fell upon the flank and rear of Antigonus's right wing and pursued it into the mountains. The phalanxes now clashed together, the Silver Shields carrying all before them. Antigonus was advised to retire, but he was too good a soldier to take this course. He noticed that the pursuit of Eumenes and the movement of the Silver Shields had created a gap between the phalanx and the left wing cavalry. Through this gap he charged, and struck Eumenes' right flank in rear driving it from the field. The battle was indecisive, and during the night both armies retired. Eumenes was now compelled to disperse his force in order to live. Antigonus, determining to take advantage of this, abandoned the main road for a little-known desert track. Learning of this, Eumenes lit fires "within the compass of 70 furlongs," which so completely deceived Antigonus that he abandoned the track, this allowed Eumenes to concentrate his forces. The armies now met, that of Antigonus numbering 22,000 foot, 900 horse, and 65 elephants, and that of Eumenes 35,700 foot, 6,050 horse, and 114 elephants (See plan below).

Eumenes, hearing that Antigonus was with his right wing, faced him with his left, in front of which he drew up in a half-moon formation, the bulk of his elephants linking them up with light infantry. In his centre he marshalled his targeteers in front, the Silver Shields behind them, and the "foreigners" in rear. In front of the targeteers he extended a line of elephants and light troops, his right wing being ordered "to retire leisurely as he fought, and

diligently to observe the events of the other side." As the elephants advanced on each other a tremendous dust was raised, under cover of which Antigonus sent out a force of cavalry to pass round the enemy's flank and seize his baggage camp. Eumenes charged forward through the dust, a large number of his horse deserting him. He was followed by the Silver Shields who once again carried all before them, but on account of the flight of Eumenes' cavalry they were surrounded by the enemy's. Learning that their baggage and wives were in the enemy's hands they were thrown into consternation. Thereupon Antigonus offered to hand their camp back to them if they would desert and surrender Eumenes. This they agreed to do, and after a week's captivity Eumenes was put to death by his guard.

To the Death of Heracles, 310 B.C.—Whilst Eumenes was warring in Asia, Olympias, the mother of Alexander, put to death Philip Arrhidaeus. Thereupon Cassander, who by bribery had won over many of Polysperchon's soldiers, besieged her in the fortress of Pydna. In the spring of 316, with Roxana and her child (Alexander's widow and son), she surrendered to him and shortly after was assassinated. The death of Eumenes having freed Antigonus from opposition in Asia, he made the assassination of Olympias an excuse to destroy Cassander. Through self preservation, Lysimachus, Ptolemy and Seleucus formed an alliance against him, and in 314, to weaken Cassander, Antigonus promised freedom to the Grecian cities. The result of this was that the Aetolians entered into alliance with him, and Cassander was forced to march against them. Meanwhile Seleucus gained over Babylonia and founded the Seleucid dynasty.

In 311, Cassander having defeated the Aetolians, a temporary peace was patched up, the terms of which were: That Cassander was to hold Macedonia until Roxana's child should come of age, Lysimachus to govern Thrace, Ptolemy to retain Egypt, and Antigonus to rule all the provinces of Asia. No sooner was this peace agreed upon than Cassander assassinated Roxana and her child, whereupon Polysperchon, influenced by Antigonus, espoused the cause of Heracles the pretender, proclaiming him Alexander's son by his mistress Barsine. Cassander, whose position was insecure, offered Polysperchon complete control of the Peloponnese if he would put Heracles out of the way, which was promptly done.

To the Death of Antigonus, 300 B.C.—To punish Cassander, in 307 B.C., Antigonus sent his son Demetrius to the Peloponnese. The Athenians mistaking his fleet for that of Ptolemy allowed him to enter the port, whereupon Athens opened her gates to him. The next three years were spent by Demetrius in a series of campaigns. At the battle of Gaza, 312 B.C., he was defeated by Ptolemy and Seleucus, captured and at once released. Concentrating his main cavalry force in his right wing, Ptolemy protected it against Demetrius's elephants by a palisade pointed with iron spikes, in front of which he placed his light infantry. As the elephants advanced they were plied with darts, and when they struck the iron spikes they were thrown into such confusion that the Demetrius lost heart and withdrew.

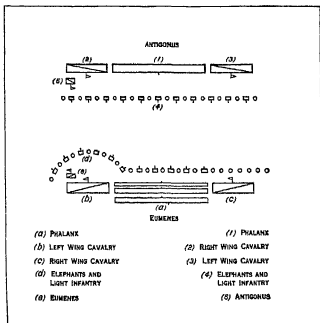

In 308 B.C. Demetrius, realizing that Ptolemy's strength lay in his command of the sea, defeated him in a naval battle off Cyprus, and in the following year he set sail for Rhodes, the siege of which was the greatest exploit of his eventful life. At this siege every type of device was made use of by besieged and besieger. Demetrius employed 30,000 artificers and workmen to build his towers and engines, Helepolis, the largest tower he built, required 3,400 men to move it. He constructed a ram 180ft long which was moved on wheels by 1,000 men. In place of ramming his enemy's war galleys, he cleared their decks by ventable broadsides of missiles, and Plutarch tells us that he built galleys of 13 banks of oars, and some of even 15 and 16 which "were as wonderful for their speed as for their size." Nevertheless, in spite of his inventive genius, in the autumn of 302 B.C. he was compelled to raise the siege, for Ptolemy, still controlling the seas, resupplied the city.

Returning to Athens, in April 301, as he was marching into Thessaly to meet Cassander, Demetrius was recalled to Asia by Antigonus. The reason for this was that Ptolemy, Seleucus and

Lysimachus, fearing that should Cassander be defeated Greece would be added to the kingdom of Antigonus, determined to relieve the pressure by attacking Antigonus in Asia. In the spring of 300 B.C. the opposing forces met at Ipsus, in Phrygia. Demetrius with the main force of cavalry charged Antiochus, the son of Seleucus, routed him, and then pursued him. Seeing what had happened Seleucus blocked his return by a line of elephants, and then in place of charging Antigonus threatened him with attack, so giving time to such of the enemy who wished to desert to come over. This a large body did, and when a strong force of the enemy drew up to charge Antigonus, one of those about him cried out: "Sir, they are coming upon you!" To which the old general replied dryly: "What else should they do?" and was at once smitten down by a multitude of darts. His kingdom was then broken up, chiefly to the profit of Seleucus.

To the Death of Seleucus, 281 B.C.—In 296 B.C. Cassander died, and Demetrius returning to Greece became master of Macedonia. There he prepared to invade Asia, which threat resulted in an alliance between Seleucus, Ptolemy and Lysimachus. Demetrius, forsaken by his troops, surrendered himself to Seleucus, who kept him a prisoner until his death in 283 B.C. In 277 B.C. his son Antigonus Gonatas regained the throne of Macedonia, and his descendants, the Antigonid kings, held it until the battle of Pydna, in 168 B.C. In 283 B.C., Ptolemy, king of Egypt, died at the age of 84, and two years later, at the battle of Corin, Lysimachus, at the age of 80, was killed by Seleucus, who himself was murdered by Keraunos, the eldest son of Ptolemy, in 281 B.C. Thus perished the last of the Diadochi.

The Art of War of the Period—In spite of their many brilliant episodes, the wars of the Diadochi constituted a period of military decadence. The first cause for this was the sudden loss of Alexander's genius, the second, the imitation by the Suc-

PLAN OF THE SECOND BATTLE BETWEEN EUMENES AND ANTIGONUS 316 B.C.

cessors of his actions without understanding them, and, lastly, the immense influx of Persian gold.

When Alexander died his art died with him, and though several of his generals showed true knowledge of the art of war and on occasion actually improved on his minor tactics, they lacked his vision, and after his death the glamour they had gathered was lost and only a dream was left, which as years passed by grew fainter and more obscure. Eumenes was an able leader, full of resources and craftiness, yet in his first battle with Antigonus he merely copied the Alexandrine tactics in place of breathing out their spirit. He made his right wing the decisive attack, as Alexander had done, but Alexander always struck at his enemy's command,

the decisive point, and as Antigonus was commanding his own right wing Eumenes should have attacked him with his left. In his second battle he does not repeat this mistake, which shows how little of essential value is learned even by intelligent soldiers until disaster hammers knowledge home.

The Persian gold, with which Alexander intended to develop his empire, was spent in war. The mercenary now came into his own, and not only was he bought and sold on the battlefield, which if it did not destroy discipline destroyed all reliance in it, but he changed the art of leadership and of military organization. A mercenary army will serve any master for pay, and when a general is forced to hire mercenaries he looks for the most formidable type of troops. In this day the sarissa armed hoplites were of this category, consequently a man who looked for employment as a mercenary knew that as a hoplite he would command higher pay than as an archer or a peltast. The result was a disruption of Philip of Macedon's organization and a steady return to the Spartan tactics.

In the army of Alexander leadership was based on heroism, but in the armies of the Diadochi it was based on pay. The result of this was that heroism was replaced by craft. Warfare, in a low and underground way became more intellectual, and leadership had to follow suit. The leader was no longer a hero but a diplomatist, and as he led by gold in place of by valour, he crept behind his men or, more frequently still, hired a hero to lead them and from a safe distance instructed him what to do. Thus the mercenary separated leadership from command, and the whole art of war changed. Another influence of gold was that warfare became mechanized. Gold stimulated invention, invention stimulated industry and industry was applied to war. Projectile weapons came more and more into use, and as they were difficult to move on the battlefield they induced generals more and more to adopt defensive tactics. The antelephant palisades at the battle of Gaza are an example of this.

The whole tendency of this period is one from prowess to cunning under the Diadochi; we see strategy steadily coming to the fore. Antipater and Ptolemy go into league against Perdiccas, and their movements, as well as their ideas, are combined. At the battle of Ipsus it is the same, and out of these various transient combinations may be seen evolved from cunning a definite conception of the balance of power, in the making and unmaking of which more and more does command of the sea play a decisive part. Ptolemy holds it, then Antigonus attempts to wrest it from him, such was the cause of the siege of Rhodes. Each king wants to secure his frontiers, and the only one who succeeds in doing so is Ptolemy—as long as he can command the sea. With this command Egypt is virtually an island. Surrounded by deserts, it is all but unassailable save from the sea. The result of this security is immense prosperity, which gives birth to an economic and ethical outlook on war. Ptolemy from a leader steps into the position of a modern commander, a true general in chief. He is a statesman, and he understands that cities may be used as a weapon—witness his treatment of Demetrius after the battle of Gaza, and this was not an isolated case. He knows the value of his immense resources, and to him they are weapons of war. He saves Rhodes by means of dried peas, and not by pikes, and plans campaigns while his generals fight his battles. Thus we see, in many unlocked-for ways, how the unleashing of the power of gold transformed civilization and with it the art of war.

The Foundations of Modern Europe.—The influence on western civilization in these 40 years of incessant war was profound. Alexander had dreamed of a world empire through a fusion of races and, curious as it may seem, it was through the wreck of his empire that this idea took form. At his death Greece and Persia disappeared and the Hellenistic world was established in their stead, a world of decadence and of progress which was destined to fertilize Rome and, later on, Arabia. As Greece had transmuted the barbaric fables of the Orient into rich gold, so they into mystic cabalistic webs into its gnosticism and theologies. Without Alexander and his successors there would have been no Christian religion nor would there have been an Arabian

civilization—in fact the world today would not be the world we know.

Grote, *History of Greece*, vol. x (1906), H. Delbrück, *Geschichte der Kriegskunst* (1908), *The Cambridge Ancient History*, vol. vi (1927), W. W. Tarn, *Hellenistic Civilization* (1927).

DIAGENESIS. After deposition, a sediment may be materially altered or modified. These modifications may occur before burial at the interface between sea water and the sediment after burial but before consolidation or after consolidation either at normal temperatures and pressures or at elevated temperatures and pressures. To those changes which take place in a newly deposited sediment, prior to its consolidation, either at or below the sediment water interface, the term diagenesis is applied. Changes in the sediment produced by higher temperatures and pressures are properly called metamorphic. There is some uncertainty where diagenesis leaves off and metamorphism begins. Some writers would restrict diagenesis to reactions taking place on the sea floor and would use the term epigenesis for those changes which occur after consolidation and uplift but prior to the advent of truly metamorphic conditions. The changes or processes operating on a sediment clearly overlap and form a continuum so that it is commonly difficult, from a study of the results alone, to be sure in which stage a particular feature was produced.

Diagenetic changes are brought about mainly by chemical reaction of the solid particles of the sediment with the surrounding fluid, either the superjacent medium from which the sediment was deposited or the fluids trapped in the intergranular voids or pores of the sediment. The processes, solution and reprecipitation and exchange of ions between solid and liquid, alter the physical properties and the chemical or mineralogic composition of the sediment.

Included among the changes are compaction—which is largely physical and results in decrease of porosity of the rock, cementation, usually by the precipitation of interstitial cement, recrystallization (such as conversion of aragonite to calcite), replacement (such as the conversion of precipitated calcium carbonate to dolomite, the double carbonate of calcium and magnesium), selective solution of some components, and the regeneration and growth of others.

Among the many products of diagenetic action are the authigenic minerals which grew in the sediment after deposition. These may occur as secondary overgrowths on pre-existing detrital grains or as crystals without detrital cores. The quartz and feldspars of some sandstones commonly show authigenic overgrowth, both may occur also as small authigenic euhedra in limestones. Some concretions, most glauconite, much dolomite, the chlorite and clay mica of shales and some cherts have been attributed in part to diagenesis.

DIAGHILEV, SERGEI PAVLOVICH (1872–1929), Russian ballet producer, was born in the province of Novgorod, Russia, March 19, 1872. After studying law and music he organized art exhibitions in St. Petersburg (Leningrad). In 1899 he founded the review *Mir Iskusstva* ("The World of Art"), to which K. A. Somov and L. Bakst contributed and which exercised a powerful influence on Russian art. From 1907 onward he occupied himself with musical and theatrical productions and organized a number of Russian concerts in Paris, there he produced in 1908 and 1909 Russian operas (*Boris Godunov* and *The Maid of Pskov*) and ballets. Subsequently he organized successful ballet and opera seasons in London, Paris, Berlin, the U.S. and elsewhere. One of his most successful operatic productions was that of Modest Musorgsky's *Khovantschina*. In England the originality of his conceptions may be said to have effected a revolution in choreographic art and further put new life into stage dancing which by the end of the 19th century had degenerated into a spectacular show of little artistic significance. Among his numerous successful ballets may be mentioned *Carnaval* (music by Schumann), *Scheherazade* (music by Rimsky-Korsakov), *Petrushka* (music by Stravinsky), *La Boutique Fantasque* (music by Rossini) and *The Three-cornered Hat* (music by De Falla)—to name but a few of

a very large number. In 1904 Diaghilev produced a valuable book on the painter D. Levitsky. A collection of photographs and drawings illustrating the ballet, *Les Biches*, was published in 1924 by B. Koshino. (See also BALLETS.) He died at Lido, Aug. 19, 1929.

DIAGNOSIS Man, because of his physical and mental ills has from time immemorial turned to the physician for aid. In the past a certain mystery or magic was associated with medical diagnosis. The modern physician, however, proceeds in a logical, rational manner, avoiding the supernatural but calling for aid not only upon medicine but also upon chemistry, physics and bacteriology. While many who are ill recover without treatment, thanks to what the ancients called the *vis medicatrix naturae*, the healing power of nature, the first step toward successful treatment is a correct diagnosis.

In making a diagnosis the physician consciously or subconsciously follows certain definite mental processes. First, he recognizes the problem which the patient presents, second, he collects data that more clearly outline the problem, third, he thinks over the facts and the possible solutions, fourth, he reasons out the implications of the suggested solutions, and lastly, he compares the actual facts with the suggestions to see if there is an identity between the facts established and the suggested solutions. These facts are obtained from the anamnesis, or history, from the physical and physical examination and from laboratory tests and the data obtained from the employment of instruments of precision such as the X-ray, the electrocardiograph, the electroencephalograph and similar instruments.

These are the methods of diagnosis whether the disease is to be treated by medical or by surgical procedure. The methods of medical and surgical diagnosis are one and the same, only the methods of treatment vary.

Patient's History—The importance of a careful history has been recognized from the earliest times. Rufus of Ephesus who practised during the reign of Trajan (c. A.D. 100), wrote a work *On the Interrogation of Patients*, which still remains one of the classics of medical literature.

In the history, the influence of heredity is often of great importance since certain physical characteristics of individuals are transmitted from one generation to another. The thin, gracile, sthenic type is more prone to develop certain diseases than is the heavy, muscular, phlegmatic individual who, in turn, is more likely to suffer from certain other diseases. High blood pressure and diabetes mellitus show a marked tendency to appear in successive generations of the same family. Cancer and tuberculosis show a marked hereditary tendency. Nervous and mental diseases are particularly prone to appear in certain families. Some diseases of the nervous system are always hereditary, familial or congenital. Friedreich's disease and Huntington's chorea are hereditary, Wilson's disease is familial, meningocele, spina bifida and many cases of hydrocephalus are congenital. Psychoneuroses show a marked familial tendency as do certain psychoses, notably manic-depressive psychoses.

Not only should the family history be carefully noted but the past history of the patient himself. Certain diseases of childhood may give the clue that indicates the correct diagnosis. For instance, the history of enlarged glands of the neck, or even of scrofula, during childhood suggests that the cough from which the adult patient suffers is caused by pulmonary tuberculosis.

The patient's occupation and habits, moreover, may offer clues to diagnosis. Certain occupations present definite health hazards. Those who work in an atmosphere of dust, such as coal miners, metal workers, stone masons and woodworkers inhale dust particles which lodge in the lungs and may later produce severe pulmonary disease. Workers in chemical plants may suffer from acute or chronic poisoning, and painters are prone to develop lead poisoning unless proper precautions are observed. Nursery workers who spray plants with solutions of arsenic, mercury and other poisonous ingredients are subject to hazards from the exposure. It is also important to know where the patient has lived or still lives. Malaria is very common in the Mediterranean area but very rare in Labrador.

The excessive use of alcohol and tobacco has long been recognized as a cause of disease. Chronic alcoholism causes certain types of psychoses. Cirrhosis of the liver, while probably resulting from a nutritional deficiency and not from a direct action of alcohol on the liver cells, nevertheless is closely associated with the abuse of alcohol, as the old designation "gun drinker's liver" indicates. More than one-half of the cases of cirrhosis of the liver in the United States are seen in alcoholics. The excessive use of tobacco plays its role in the production of disease, particularly of the vascular system. Tobacco causes, in many individuals, a constriction of the capillaries of the skin with a lowering of skin temperature, while other individuals develop cardiac irregularities from excessive smoking. The patient's eating habits, his favourite foods, foods that agree or disagree with him suggest possible diagnoses. The patient with hyperacidity of the stomach cannot eat pickles, while the man with too little acidity enjoys them. So much for the patient himself.

History of the Illness—Next, the physician investigates the history of the patient's illness. He inquires as to the symptoms, general or local, if local, where localized. Since the local symptoms are most commonly pain the physician wishes to know where it is located, whether it is constant or occasional, whether it is sharp or dull, whether it remains localized or travels to another region. In many diseases, such as angina pectoris, duodenal ulcer, intermittent claudication and tabes dorsalis, an accurate description of the pain, its location, duration, periodicity and the conditions under which it appears or disappears, is often sufficient to indicate the diagnosis. The duration or chronicity of the disease is always investigated. Some diseases are acute some are chronic, some tend to spontaneous recovery, others never recover, with or without assistance. Lobar pneumonia is an acute disease in which recovery or death occurs in a few days. A patient who has been ill a month or longer is not suffering from uncomplicated lobar pneumonia. Conversely, diabetes mellitus is a chronic disease in which complete recovery rarely if ever occurs. A patient who has had sugar in the urine which later completely disappeared probably does not have diabetes.

History taking is an art of inestimable value. Some physicians estimate that the history itself contributes 50% to the correct diagnosis, others raise the percentage as high as 75. Hippocrates, the father of medicine, has left case histories of patients described so accurately that 2000 years later we can read a history and make the correct diagnosis.

Physical Examination—Having obtained the history of the patient and of the disease, the physician next proceeds to examine the patient, using his trained senses of sight, touch, hearing and smell. In this physical examination he employs four methods: (1) inspection, (2) palpation, (3) percussion, and (4) auscultation.

Inspection—This is the oldest of these methods and practically the only one employed by ancient and mediæval physicians, aided at times by palpation. It is, however, remarkable how much the trained eye can reveal without even questioning the patient. Sir Arthur Conan Doyle, who was a physician, tells us that Sherlock Holmes was inspired by one of his teachers, Dr. Joseph Bell, whose uncanny powers of observation made an indelible impression upon the young medical student. Jean Nicholas Corvisart, the celebrated physician of Napoleon I, while examining a portrait one day remarked, "If the painter has been accurate, the original of this picture died of heart disease." Subsequent investigation proved he was correct.

Inspection alone may be sufficient to diagnose diseases causing alterations in the patient's appearance, such as acromegaly which produces marked enlargement of the jaws, nose and frontal bone or leprosy which of course causes thickening of the tissues of the face so that the patient's face actually resembles that of a lion—the leonine facies. The expression of the face is characteristic of certain diseases. In Parkinson's disease the face is often singularly devoid of expression, masklike—the so-called Parkinsonian mask. In paralysis of the facial nerve, Bell's palsy, the patient is unable to close his eye and/or show his teeth on the affected side. The gait of the patient may be characteristic of a certain disease, such

as tabes dorsalis, hemiplegia or paralysis agitans

The eyes may be protruded or sunken, the pupils may be irregular not of the same size in each eye, may not constrict when exposed to light—all of these abnormalities having especial significance. Inspection of the blood vessels of the neck, the carotid artery and the jugular vein may reveal irregularities in the beat of the heart so characteristic as to indicate the diagnosis. Inspection of the chest may reveal a marked difference in size and inequality of respiratory movements on the two sides, and the apex beat of the heart reveals by its position whether the heart is enlarged and by its character whether the heart is irregular. An enlarged stomach, liver or spleen or a tumour in the abdomen are often readily seen on careful inspection.

The ancients devoted a great deal of attention to the pulse and wrote many tomes on the subject. Paul of Aegina, who practised during the 7th century A.D., distinguished 62 varieties of pulse. While the modern physician thinks that many of these varieties were figments of the imagination, he has found that certain diseases are almost invariably associated with a certain type of pulse and that certain heart diseases have pulses that are slow or fast, small or bounding, regular or irregular.

Palpation—By palpation, the physician confirms what is seen on inspection. Firmness or softness, irregularity in outline or of the surface of an enlarged organ may not be apparent on inspection alone. Pain may be elicited on pressure and oedema of the ankles, which has been suspected on inspection, is confirmed when pressure with the finger produces a pitting which persists. Palpation may reveal tenderness over the gall bladder in gall-bladder disease and tenderness on pressure over the appendix is diagnostic of appendicitis unless the symptoms and the other findings disagree with this diagnosis. Palpation is of great value in the diagnosis of suspected fractures revealing abnormal motility of the bones or crepitation. After palpation the physician proceeds to percussion.

Percussion—Percussion, or tapping with the fingers, was discovered by Leopold Auenbrugger and described in his *Invention Noveum*, one of the classics of medical science, published in 1761. Auenbrugger, the son of an innkeeper in Graz, learned as a boy to tell how much wine there was in a cask by tapping on the end. As a physician he discovered he could tell which side of the chest contained fluid by tapping on it and that he could determine the size of the heart, the presence of fluid, pneumonia and other disease processes by this method.

Percussion of the chest reveals whether the lungs are air-containing or consolidated, whether pneumonia or pulmonary tuberculosis should be suspected, as well as whether fluid in the chest or thickening of the pleura or air in the chest may be present. Percussion is important in determining the position and the size of the heart, liver, spleen and stomach. Its value is greatly enhanced by auscultation.

Auscultation—Auscultation, or listening, was the discovery of René Theophile Hyacinthe, Laennec, a pupil of Corvisart, who introduced percussion into medical practice in France. Laennec, according to his biographers, was watching a group of children playing on a dorm in the courtyard of the Louvre. One youngster "scratched the beam with a pin and the other, ill at ease, pressed against the beam till every time he scratched, Laennec, on his way to see a patient, had no inspiration. On reaching the patient's house he took a sheet of paper, rolled it into a cylinder, applied one end to his ear and the other end to the patient's chest. To his delight he heard the heart sounds perfectly and at that moment the stethoscope was discovered. He described his instrument and its value in his *De l'Auscultation médiate*, published in 1819. The stethoscope remains one of the indispensable aids in the diagnosis of disease of the lungs and heart. With it the physician determines whether the breath sounds are normal or whether there are signs of inflammation, bronchitis, consolidation or cavitation in the lungs. He also can tell whether the heart sounds are normal or whether there is disease of the myocardium (lesions of the four sets of heart valves). (See APPENDIX A.)

Instruments of Percussion—After the physical examination has been finished, the physician turns to instruments of percussion

for additional aid.

Sanctorius (1561-1636), professor at Padua, was the first physician to employ instruments of precision in the practice of medicine. Galileo, watching the swinging of the lamp in the cathedral of Pisa, counted its oscillations by feeling his pulse and established the law of the isochronism of the pendulum. Sanctorius, his colleague and friend, reversed the process and timed the pulse by the swinging of a pendulum employing a weight attached to a cord. The length of the cord, which was adjusted until the rate of the oscillation agreed with that of the pulse, was measured on a scale and this taken as the pulse rate. Sanctorius also employed the thermometer, probably invented by Galileo, to determine the patient's temperature and weighed his patients on a steelyard to measure accurately the effect of food, exercise and various activities upon what he called the insensible perspiration. His steelyard was a forerunner of the basal metabolism instruments now so widely employed in medicine.

Although Sanctorius published his method of estimating the pulse and determining the temperature in 1625 and his work on insensible perspiration in 1614, only the latter made much impression upon medical thinking. Accurate timing of the pulse first became a recognized procedure when Sir John Floyer published in 1707 his *Pulse Watch*, in which he stated he at first employed a sea minute glass such as was used by mariners "but because that was not portable, I caused a Pulse Watch to be made which runs 60 Seconds, and I placed it in a Box to be more easily carried, and by this I now feel Pulses."

Registration of the temperature lagged even further behind, the first systematic recording dating from 1852 when Ludwig Traube published the first temperature curve in fever from the Leipzig clinic.

Sir James Mackenzie (1853-1925), while a general practitioner in Burnley, Eng., devised an instrument with which he could simultaneously register the pulse waves in the radial artery at the wrist and in the jugular vein in the neck. By comparing the two sets of curves, the jugular pulse indicating the action of the auricles and the radial pulse the changes in the ventricles, he demonstrated the mechanism by which irregularities of the pulse were produced and made some of the most noteworthy contributions in the history of cardiology.

Blood Pressure—Taking the blood pressure is an important feature in the examination of the patient. While the skilled physician in the past could tell whether the blood pressure was elevated by palpating the pulse, this method was inexact and often misleading. In 1896 Scipione Riva Rocci devised the instrument in use today, a rubber bag surrounded by a cuff, which is pumped up until the pulse disappears at the wrist—the systolic pressure. Later it was found that by listening at the bend of the elbow, systolic pressure as well as diastolic pressure could be estimated. The systolic pressure is the pressure during the systole or the beat of the heart, the diastolic pressure that during diastole or the pause or the heart between beats.

Although there is still much discussion regarding the normal systolic and diastolic pressures, it is safe to state that a systolic pressure of more than 140 mm of mercury and a diastolic of more than 90 mm is elevated.

Electrocardiograph—No study of the heart or circulation is complete without the records obtained with the electrocardiograph. Augustus D. Waller in 1887 showed that an electrical current produced by the beating of the heart could be demonstrated in man by attaching electrodes to the body and connecting them with a capillary electrometer. Willem Einthoven in 1903 substituted for the capillary electrometer a string galvanometer of his own design, and the electrocardiograph became a practical clinical instrument. In the original instrument the feeble current coming from the body through the arms and leg was carried into a quartz string placed in a magnetic field. Each heartbeat causes a vibration of the string whose movements are photographed on a moving film or sensitized paper—the electrocardiogram. Later improvements consisted of employing tubes similar to those used in radio which step up the weak current until it moves a more sturdy string but the original delicate quartz fibre, or even marks directly upon

prepared paper. The latter method avoids the inconvenience of photography and allows the physician to watch the record as it is being written.

The information obtained from study of the electrocardiogram is amazing. It shows whether the heart is enlarged, where the enlargement occurs, whether the heart action is irregular and where the irregularity originates, whether an occlusion of a coronary vessel is present and if so where the occlusion is located, whether a slow rate is physiological or caused by heart block. It also indicates high blood pressure, thyroid disease and certain types of malnutrition.

Electroencephalograph—One of the latest instruments of precision, the electroencephalograph, was first described in 1929 by Hans Berger of Jena. It records the electrical activity of the human brain and has been of especial value in the diagnosis of epilepsy and in the location of lesions of the brain, such as tumours, abscess or haemorrhage.

X rays—No method of examination has given greater aid in the field of general diagnosis than the X-rays or Röntgen rays, discovered by Wilhelm Konrad Röntgen in 1895. Three months after the discovery the *Journal of the American Medical Association* wrote, somewhat pessimistically, "Half an hour is the shortest exposure possible and most require one hour. The electric apparatus required is so expensive, \$100 and upward, that few surgeons can use it yet in their private practice." After that time the X-ray was improved so that exposures require only fractions of minutes but, needless to say, the cost of the apparatus has enormously increased.

The original X-rays were photographs made on sensitive plates. With the development of fluoroscopy, X-ray diagnosis became even more helpful. When a patient is placed in front of the X-ray tube and behind the fluorescent screen, the physician sees clearly the outlines of the body, can watch the heart beat and note any irregularities, and can watch the lungs expand in respiration and observe whether this expansion is normal. When the patient swallows a gruel containing barium or any other substance opaque to the X-ray, the physician can follow by the shadow it casts its course from the mouth through the oesophagus, stomach and into the intestines. The X-ray demonstrates the structure of the bones of the body and lesions of the bone such as defects of structure, fractures, tumours, arthritis and inflammations. It reveals the size of the heart, irregularities and defects of the heart, pulmonary diseases such as bronchitis, pulmonary tuberculosis, collapse and abscess of the lungs, tumours of the lung, thickening of the pleura, fluid in the pleural cavity, enlargement of the liver, spleen and kidneys and stones in the kidneys, gall-bladder, bladder and pancreas.

The employment of contrast mediums, opaque solutions casting shadows, greatly enlarged the scope of X-ray diagnosis. This method made possible the demonstration of bronchiectasis of the lungs, diverticula and cancer of the oesophagus, ulcers and cancer of the oesophagus, stomach and intestines, and lesions of the kidneys, ureters and bladder. Similarly, the employment of tetraiodo phenolphthalein, introduced by Everts A. Graham and W. H. Cole in 1924, a dye which is excreted in the gall-bladder and casts a shadow, demonstrates enlargement of the gall-bladder and lack of function or the presence of gall stones. Ventriclegraphy, introduced by Walter E. Dandy in 1918, consists of introducing air into the ventricles of the brain and then taking an X-ray of the skull. The resultant picture shows the size and location of the ventricles which may be displaced or distorted by a tumour or abscess of the brain. (See RADIOLOGY.)

Basal Metabolism Tests—Another method of examination, the basal metabolic test, is of great value in certain patients. The method employed consists of estimating the amount of oxygen consumed in a certain amount of time. When more oxygen than normal is consumed, the metabolic rate is increased, when less, it is decreased. It is of especial value in the diagnosis of thyroid disease. In hyperthyroidism or exophthalmic goitre the metabolic rate is increased, in hypothyroidism, decreased. (See NUTRITION Metabolism.)

Other Instruments—In addition to these instruments of pre-

cision, the physician also has at his disposal the ophthalmoscope which permits inspection of the retina, the bronchoscope, which shows the interior of the bronchi, the gastroscope, which gives a clear view of the interior of the stomach, the laryngoscope, for studying the larynx and vocal cords, the cystoscope which visualizes the interior of the bladder, and the proctoscope, which demonstrates lesions of the rectum and sigmoid.

Laboratory—After the physician has completed the physical examination and his examination with instruments of precision he turns next to the laboratory for study of the blood, urine, body fluids, secretions and any tissue which was removed for microscopic examination. The blood is examined the number of red cells and white cells are counted the haemoglobin or colouring matter of the red blood cells is determined the white blood cells are then stained and the relative percentage of the different types estimated. In the anaemias, the number of red cells is decreased, in polycythaemia increased. In most infectious diseases the number of white blood cells is increased, but in some infectious diseases a decrease in the number of white blood cells is a characteristic feature. In the leukaemias, the number of white blood cells is often tremendously increased. The clotting time of the blood is delayed in haemophilia, the formation of the clot is often abnormal in purpura. The blood platelets, a third type of blood cell, are markedly diminished in numbers in purpura haemorrhagica. Blood typing is of the greatest importance in certain conditions and in connection with treatment by transfusion. Estimations of the sedimentation rate of the red blood cells are routine in many physicians' offices.

The blood serum yields important information in many diseases. It contains substances in syphilis which produce a positive Wassermann reaction and specific agglutinins in typhoid fever which agglutinate the typhoid bacillus (Widal reaction) and specific agglutinins in brucellosis (undulant or Malta fever), tularaemia and other less common infections. Blood cultures are a routine in many infectious diseases and may demonstrate the presence in the circulating blood of the typhoid bacillus, the pneumococcus, the meningococcus and the streptococcus, to mention a few well-known examples.

Studies of the blood chemistry are of great importance in many diseases. In diabetes, for example, the amount of sugar in the blood is greatly increased, and in nephritis (Bright's disease), the kidney being unable to excrete properly, the blood values for urea, uric acid and creatinin may rise sharply. In hyperthyroidism, the blood cholesterol may be diminished and in hypothyroidism, greatly increased. In many diseases a study of the patient is incomplete without certain determinations of the blood chemistry.

By means of the stomach tube, the physician is able to study the gastric contents. The most important finding is the degree of acidity present. In gastric or duodenal ulcer the gastric acidity is usually much increased, in cancer of the stomach decreased, while in pernicious anaemia there is no acid present.

Functional Tests—These tests are assuming increased importance in diagnosis. The functional capacity of the heart is tested by noting the increase in the heart rate and in the blood pressure following exercise, and also by recording the time necessary for both to return to their normal values. Tests for the function of the kidneys are carried out by noting the rate at which the dye phenolsulphonphthalein when injected in the cubital vein is excreted in the urine and by the urea clearance test in which the blood urea and the amount of urea present in 75 cc of blood is estimated. Functional tests for the liver employ the injection of dyes intravenously, such as bromsulphalein which is entirely withdrawn from the circulation by the liver in normal persons in 30 min. Carbohydrate function tests are performed by giving the patient 100 g of glucose by mouth on an empty stomach. Normally the blood sugar rises sharply from the normal of 100 mg per 100 cc to 150 mg or 160 mg, then falls sharply and is down to its original level in two hours. In diabetes mellitus it may rise to two or three times its normal value and remain quite high for two, three or even four hours.

Cutaneous, or skin tests, are valuable in diagnosis. When the skin is scratched and a drop of tuberculin is placed on the spot, an area of redness with induration of the skin appears in from 24 to 48 hours in persons who have or have suffered from tuberculosis (Von Pirquet test). This test is of especial value in children. Similarly, when a drop of diphtheria toxin is employed, individuals who have no immunity to diphtheria show a reaction (Schick test). A similar test is employed in the allergic diseases, notably asthma and hay fever, where the offending material, such as milk, wheat, horse serum, ragweed pollen, etc., causes a reaction.

In many patients an examination of pathological sections for

baeteria may be a deciding point in diagnosis. The exudate from an inflamed tonsil, pharynx or nostrils when stained by proper methods may reveal the diphtheria bacillus or the streptococcus as the cause of the disease. Cultures of such secretions or from the urine, faeces, pus or sputum demonstrate the organism even more conclusively. The demonstration of a single tubercle bacillus in the sputum makes positive, often, a suspicion of pulmonary tuberculosis.

Final Diagnosis.—The physician has now collected his data. This is the most painstaking and laborious stage in his search for the correct diagnosis. He now thinks over the facts that he has obtained and the suggested solutions—sugar in the urine, for instance, would suggest diabetes mellitus. Then he reasons out the implications of the suggestions, thus a diabetic patient in addition to sugar in the urine should have an abnormal amount of sugar in the blood, should have a history of excessive thirst, excessive urination and loss of weight.

The physician next arrives at the last stage of the mental processes required in making a diagnosis. He comprises the actual facts with the suggestions that have occurred to him to see if there is an identity between such facts and the suggested solutions. If further study brought out the existence of all of the above symptoms, the actual facts would agree with the suggested solution. The diagnosis would be diabetes.

This is the method pursued by the physician in making a diagnosis. While the task of collecting data on the patient, the history, the physical examination, special examinations and laboratory tests require accurate observation, the above process of correct reasoning is, in the last analysis, more important. To assemble the data, to make use of the relevant and to discard the irrelevant and to pass final judgment or make a diagnosis often require a mental ability of the highest order. It is the final test of the physician's diagnostic ability. False diagnosis often result not from false data but from faulty interpretation.

(R. H. M.)

DIAGONAL, in geometry, a line joining the intersections of two pairs of sides of a rectilinear figure (Gr. *diá*, through, *gonia*, a corner).

DIAGORAS, of Melos, surnamed the Atheist, poet and sophist, flourished in the second half of the 5th century B.C. Religious in his youth and a writer of hymns and dithyrambs, he became an atheist because a great wrong done to him was left unpunished by the gods. In consequence of his blasphemous speeches, and especially his criticism of the Mysteries, he was condemned to death at Athens, and a price set upon his head (Aristoph. *Clouds*, 850, *Birds*, 1073 and Schol.). He fled to Corinth, where he is said to have died. His work on the Mysteries was called *Apology* *Apology* or *Apology* *Apology*, in which he probably attacked the Pythagorean doctrine.

DIAGRAM, a figure drawn so that geometrical relations among its parts illustrate relations among the objects represented by the figure, supplemented sometimes by numerical or other entries on the figure itself to show relations not represented graphically by the figure. The purpose of a diagram is to present vividly to the eye the principal relations on which one desires to fix attention and even sometimes to show by measurements on the figure, the exact numerical values of certain important quantities associated with the object which it represents. Owing to the generality of the concept, diagrams are useful for a great variety of specific purposes.

Mathematical Diagrams.—In mathematical treatises diagrams are used principally to help the reader follow the reasoning. Figures are drawn to represent to the eye the relations among the parts involved in a proposition to be proved and in the auxiliary propositions employed in the demonstration. In the proof itself attention is directed from the relations which are relevant to the matter in hand so that the demonstration is made general and is quite independent of the extraneous properties involved in the form of the particular figure employed. The construction of the

figure is usually so well defined in words that the reader could easily draw one for himself if the author did not supply it. Such a diagram is a good one if it sets forth clearly those features which are involved in the proposition to be demonstrated.

Diagrams in Chemistry and Crystallography.—John Dalton (*q. v.*) published many diagrams setting forth his conception of the configurations of the atoms in a large number of common chemical compounds, and the method has since been widely used by chemists. It has been found that there are many pairs of substances such that the two substances in a given pair have the same molecular formula while they differ widely in some of their properties. This difference of properties, where there is identity of molecular formulae and where we are forced to admit the same atomic linking, can be explained only by ascribing the difference to a different space distribution of the atoms in the molecule. This has given rise to the development of a branch of chemistry dealing with stereo isomerism, a subject in which space diagrams of the positions of atoms play an important rôle in the explanation of structure. Similarly, in crystallography (*q. v.*) diagrams are likewise employed freely in the explanation of crystal structure. In recent years we have had a like analysis of atomic structure itself by means of diagrams. It is important to remember that in many cases such diagrams are suggestive only of certain selected relationships in the subject—not at all literal portrayals as in architecture (see *DRAWING, ENGINEERING*), or where tangible objects are shown with measurements.

Diagrams Showing Measurements.—In a different way, diagrams may be used for purposes of measurement, they are then called *metrical diagrams*. The plans and designs of architects and engineers, necessarily drawn to scale and made as accurate as possible, are employed in determining dimensions of the objects represented, by measuring the lengths of corresponding lines in the diagrams. Such diagrams serve a purpose beyond that of mere illustration, they afford a means of actual measurements relating to the objects themselves. They are strongly contrasted with diagrams of illustration, which are suggestive merely and need not show the forms of the parts provided only their relevant connections are properly exhibited. Of the latter kind are many diagrams in the mathematical subject of analysis situs (see *TOPOLOGY*) and also those employed to show electrical connections, as in the descriptions of radio receivers. Geographical maps afford examples of diagrams of still another sort. In these the distances and relative positions among places on the earth are exhibited by their positions on the maps. By means of colours important features of various areas are often indicated, as, for instance, their political connections, or their geological character, or the distribution of rainfall or other climatic features, or the distribution of terrestrial magnetism, or the variation of elevation above sea level. The heights of places above sea level are often indicated also by the insertion of numbers on the map to indicate the number of feet above sea level of each place indicated. Another (and more effective) method is that in which a line called a contour line is drawn through a place on the map having the same height above sea level. When such contour lines are drawn sufficiently close together and numbered, then a marked in one or more places with a number to denote the height above sea level of the place, the height of the place may be obtained from a precise information concerning the contour lines of the surface of the country. In this method the diagram is partly graphical and partly symbolic and so it things are presented by the contour lines and accompanying numbers which are not shown by the relations among the parts of the diagram itself.

Diagrams for Objects Having Three Dimensions.—It is possible to use a system of diagrams for the graphical representation of the relations among any set of magnitudes involving more than two variables. In particular, to represent the relations among the parts of an object having a distribution in three dimensions, we may employ two or more diagrams, each of the two showing the relations of parts in a single plane or plane section of the object. Thus construction engineers employ plans and elevations and sections in different planes. In such a system of diagrams a definite indication must be given of the way in which the diagrams

DIAGONAL OF CUBE

DIAGONALS OF A COMPLETE QUADRILATERAL

DIAGONALS OF A PENTAGON

DIAGONALS OF A RE-ENTRANT QUADRILATERAL

are severally related to the structure as a whole and to each other. Examples of this type are afforded by the plans for buildings or for bridge construction. (See BRIDGES, DRAWING, ENGINEERING.) But it is also possible to represent solids and other figures in three dimensions by means of a single diagram drawn in a plane. One of the objects of descriptive geometry (*q.v.*) is to develop methods for attaining this end. The stereoscope (*q.v.*) furnishes a means for the use of two diagrams for the representation of three dimensional objects in such a way that their forms are readily recognized. The two diagrams are two plane projections of the bodies taken from separated points of view which are very near to each other. These two plane figures are nearly alike, their difference being due to the difference in point of view. When these two figures are placed in the stereoscope one of them is seen with one eye and the other with the other eye, in such a way that we intuitively identify the corresponding parts of the two figures. In pure geometry the method of projections, which underlies the diagrams used in the stereoscope, has led to many extensions of the science. In fact on it are founded the principles and results of projective geometry (*q.v.*).

Diagrams in Mechanics—It is probably in mechanics (*q.v.*), both theoretical and applied, that diagrams have been used for the greatest variety of specific purposes. Their application to statics is particularly convenient, owing to the fact that there is no motion of parts in a statical system. Consequently there has arisen an important branch of knowledge under the name of graphic statics. In the *diagram of configuration* it is convenient to represent the objects by points and to denote their relative positions by means of the relative positions of these points. This method is also applicable to the case of bodies in motion, the diagram of configuration then representing the relative positions of the objects at a given instant. If several diagrams of configuration are constructed, one for each of several given instants of time, then, by a comparison of these diagrams, it is possible to see the relative displacements which have taken place in the various intervals of time involved, but the system of configurations will not give the details of the motion during the interval between two consecutive instants for which diagrams of configuration have been constructed. As an example of a different kind, let us consider the diagram in fig. 1. This is a parallelogram formed from two directed lines AB and AC , issuing from a common point A , by drawing the related lines CD and BD . Attention is also placed on the directed diagonal AD issuing from A . We may use AB to denote a force applied to an object at A , the direction of AB representing the direction in which the force acts and the length of AB denoting the magnitude of the force. Similarly, AC will denote, in magnitude and direction, another force operating upon the same object at A . In mechanics it is shown that these two forces operating upon the body at A are equivalent, so far as their effect upon A is concerned, to a single force operating in the direction of the diagonal AD and of a magnitude represented by the length of AD . Thus a simple diagram enables us readily to find the (so called) resultant force AD which is equivalent to the two given forces AB and AC .

Now BD is equivalent, in direction and length, to AC . Hence we might think of the resultant force AD as the third side of the triangle determined by the given forces AB and BD , where it is understood that the force represented by BD operates at A . Then we may call ABD the *triangle of forces*, whereas $ABDC$ would be called the *parallelogram of forces*. Now the triangle of forces is capable of a ready generalization, which we shall describe by aid of fig. 2. Let several forces all operate upon an object at A , and let the magnitudes and directions of these forces be respectively AB, BC, CD, DE , placed end to end as in the figure. (These lines may or may not be in one plane.) Then AE will represent, both in magnitude and direction, a single force which is equivalent, in its effect upon the object at A , to the combined effects of the several forces denoted by AB, BC, CD and DE , respectively. This figure $ABCDE$ is called a *polygon of forces*. If there is added to the

system of given forces already described a single force EA acting upon A but having the direction and magnitude denoted by EA , then the new system of forces will be in equilibrium in the sense that their combined effect upon the object A will be to leave that object undisturbed in position. The diagram afforded by the polygon of forces furnishes one of the most important means in mechanics for the analysis of the relations of forces.

Now the meaning of a diagram depends upon the point of view from which one considers it. This is well illustrated by the dia-

FIG. 2

grams afforded by figs. 1 and 2, as we shall now show by giving interpretations of them in terms of velocities and accelerations. If AB and AC in fig. 1 denote velocities, both in magnitude and in direction, then AD denotes the resultant velocity. Thus if AB denotes the velocity of a ship relative to the earth and if AC denotes the velocity with which one is walking relative to the deck of the ship, then AD will represent, both in magnitude and in direction, the velocity of the walker relative to the earth. The combination, or *composition*, of several velocities is represented in a similar way by the polygon in fig. 2. Again, if AB and AC in fig. 1 denote accelerations, then AD denotes the resultant acceleration which is equivalent to a combination of the two given accelerations, and this may of course be extended to the case of the polygon of accelerations. These diagrams afford one of the most important means for the investigation of velocities and accelerations.

Work and the Indicator Diagram—If AB , in fig. 3, represents the path of a moving body and if for each position P of that body the force acting upon it, in the line of motion and opposed to its motion, is represented in any convenient scale by the length of the perpendicular PO from AB to the curve CD , then the area of the figure $ABDC$ represents (in a corresponding scale) the work required to be done upon the moving body during its motion from A to B .

If the piston of an engine is moving back and forth along the line AB in fig. 4 and if the area $ABDEC$ represents the work done on the piston in moving from A to B while the area $ABDC$ represents the work done by the piston against retarding forces on its return stroke, then the area $CDEBC$ will represent the effective work which may be accomplished by the piston thrust in a single back and forth motion. The figure by means of which this effective work done by the piston is shown is known as the *indicator diagram* of the motion of the piston. It is of fundamental importance in analysing the effective working capacity of the engine.

Other Diagrams—Brief definitions of various other diagrams will now be given. In an *Argand diagram* the complex numbers $x+yi$ are represented by corresponding points (x, y) with reference to a system of rectangular co-ordinates in a plane. An *automatic diagram* is one which is constructed automatically by a machine to show the related variations of two variables, as, for instance, the change of temperature with time during the day,

FIG. 3

in these cases the completed diagram often consists of a graph drawn automatically upon specially prepared co-ordinate paper. In many cases of this sort a piece of paper is made to move (uniformly or otherwise) in a given direction, let us say horizontally, while a tracing pencil unit is made to move vertically across it, the height of the tracing point varying proportionately to the magnitude of the quantity whose variation is to be registered. Machines of this sort are employed for the automatic registration of phenomena of many kinds, from those in meteorology and the theory of magnetism and electricity to those connected with the movements of plants and animals.

An *entropy diagram* shows the change of entropy in a thermodynamic cycle. *Euler's diagram* gives a graphic representation of logical relations, circles or other figures being used to denote (by their enclosed surfaces) the classes of objects to which given prop-

rates apply, many other logical relations have also been denoted by various diagrams. In a *frame diagram* the positions of joints are shown by points and the connecting links by lines, it is often united with a diagram of forces showing the components of force through the various joints. *Herz's diagram* represents the changes of temperature, pressure and moisture of a given mass of air when its volume is changing adiabatically, and *Neuhoff's diagram* is analogous to it. In *Newton's diagram* colours are represented by points, with weights attached to them to denote intensities of luminosity, while the arrangement of points is such that those which are on the same straight line can be produced by the mixtures of two colours. The *Pascuex diagram* is a certain collocation of points employed in mathematics in the study of functions. In two *reciprocal diagrams* each point of junction of lines in either diagram corresponds to a closed polygon in the other.

A *strain diagram* is a figure which shows the relation between the amount of stress applied by pressure or otherwise to a test piece of material and the strains which it undergoes on account of this stress. It is usually drawn automatically by means of an instrument attached to the machine and the piece being tested, the deformations being amplified by aid of a suitable mechanism. A *stress diagram* is a figure in which each joint of a framework is represented by a funicular polygon (such a figure as is formed by a string supported at the ends and acted on by several pressures), while each link in the frame is represented by a line belonging to one or more of the funicular polygons, it is also called a *funicular diagram*. A *variation diagram* sets forth the changes in the indicator diagram of an engine for successive strokes of the piston, it is used to determine whether the governor is acting properly. The word *diagram* is also used in numerous other combinations many of which are self explanatory.

Diagrams appear in literature mainly as incidental to the subjects in connection with which they are employed, as has been indicated in the course of the article. Consequently the bibliographies are to be found by consulting the articles dealing with these subjects.

(R D CA, 'C')

DIALA, the largest tributary of the Tigris rises in the Persian highlands near Mervan and, for a short distance south of Haleboja, forms the Perso-Iraq frontier. It joins the Tigris just south of Baghdad. After leaving the Jebel Hamra the river runs over shingle deposits and is extensively used for irrigation. The principal canals are the Beled Ruw and the Khorrassan on the left bank and the Khulis and its branches on the right. Baquba lies at the end of the Khorrassan canal, 52 miles from the mouth. This region is extremely fruitful and the river is navigable as far as this point from December to April. The metre gauge railway operating from Baghdad to Kirkuk runs along the valley of the Diala and offers a further outlet for the development of this well watered region.

DIAL and DIALING Dialing, sometimes called gnomonics, treats of the construction of sundials, that is of those instruments either fixed or portable, which determine the divisions of the day (Lat *diēs*) by the motion of the shadow or some object on which the sun's rays fall. It must have been one of the earliest applications of a knowledge of the apparent motion of the sun, though for a long time men would probably be satisfied with the division into morning and afternoon as marked by sun rise, sun set and the greatest elevation.

History.—The earliest mention of a sundial has been thought to be found in Isaiah xxxviii 8 "Behold, I will bring again the shadow of the degrees, which is gone down in the sundial of Ahaz, ten degrees backward." But a more correct translation may be "down the steps of Ahaz, 10 steps backwards." The date of this would be about 700 years before the Christian era, but there is no evidence that there was a sundial. The earliest of all sundials of which we have any certain knowledge is a \perp -shaped Egyptian dial in the Berlin museum, in which the upright of the \perp throws longer or shorter shadows along the horizontal limb which is divided into six hours. Another early classical type was the

hemicycle, or hemisphere, of the Chaldean astronomer Berosus, who probably lived about 300 B.C. It consisted of a hollow hemisphere placed with its rim perfectly horizontal, and having a style, the point of which was at the centre. So long as the sun remained above the horizon the shadow of the point would fall on the inside of the hemisphere, and the path of the shadow during the day would be approximately a circular arc. This arc, divided into 12 equal parts, determined 12 equal intervals of time

FIG 1—EARLY EGYPTIAN SUNDIAL OF PERIOD OF THOTMES III c 1500 B.C.

In the morning the crosspiece was turned to the east and in the afternoon to the west.

for that day. Now, supposing this were done at the time of the solstices and equinoxes, and on as many intermediate days as might be considered sufficient, and then curve lines drawn through the corresponding points of division of the different arcs, the shadow of the bead falling on one of these curve lines would mark a division of time for that day, and thus we should have a sundial which would divide each period of daylight into 12 equal parts. These equal parts were called *temporary hours*, and, since the duration of daylight varies from day to day, the temporary hours of one day would differ from those of another, but this inequality would probably be disregarded at that time, and especially in countries where the variation between the longest summer day and the shortest winter day is much less than in our climate.

The dial of Berosus remained in use for centuries. The Arabians, as appears from the work of Albategnius, still followed the same construction about the year A.D. 900.

Herodotus recorded that the Greeks derived from the Babylonians the use of the gnomon, but the great progress made by

FIG 2—HEMICYCLIC DIAL FOUND IN POMPEII IN 1854

the Greeks in geometry enabled them in later times to construct dials of great complexity and ingenuity. Ptolemy's *Almagest* treats of the construction of dials by means of his *analemma*, an instrument which solved a variety of astronomical problems. The constructions given by him were sufficient for regular dials, that is, horizontal dials or vertical dials facing east, west, north, or south, and these are the only ones he treats of. It is certain, however, that the ancients were able to construct declining dials, as is shown by that most interesting monument of ancient gnomonics—the Tower of the Winds at Athens. This is a regular

octagon, on the faces of which the eight principal winds are represented, and over them eight different dials—four facing the cardinal points and the other four facing the intermediate directions. The date of the dials is apparently coveal with that of the tower, for there has been found at Tenos a marble block with similar dials inscribed with the name of Andronicus Kyrresthes, the builder of the tower. The hours are still the temporary hours or *hectemoria*.

The first sundial erected at Rome was in the year 290 B.C., and this Papius Cursor had taken from the Samnites, but the

may reasonably suppose that the new sundials came into general use during the 14th and 15th centuries.

Among the earliest of the modern writers on gnomonics was Sebastian Munster (*q.v.*), who published his *Horologiorum* at Basle in 1531. He gives a number of correct rules, but without demonstrations. Among his inventions was a moon-dial. A dial

FIG. 3.—PORTABLE ANALEMMATIC SUNDIAL OF THE 16TH CENTURY. This consists of two dials. When they have been so adjusted that the two readings agree, the correct time is indicated.

first dial actually constructed for Rome was made in 164 B.C., by order of Q. Marcus Philippus. Vitruvius mentions 13 kinds of dials, including portable dials, the most interesting examples of which are the "Ham" dial, excavated at Herculaneum and the adjustable circular dial in the Lewis Evans collection at Oxford.

The Arabians were much more successful. They attached great importance to gnomonics, the principles of which they had learned from the Greeks, but they greatly simplified and diversified the Greek constructions. One of their writers, Abu'l Hassan, who lived about the beginning of the 13th century, taught them how to trace dials on cylindrical, conical, and other surfaces. He even introduced *equal* or *equinoctial* hours which were used for astronomical purposes while the temporary hours alone continued in use.

FIG. 4.—ROMAN PORTABLE DIAL. Portable dials were generally of pocket size. The one above dates from about A.D. 250 and has adjustments for the seasons and for latitude from 30° to 60°.

The great and important step already conceived by Abu'l Hassan, and perhaps by others, of reckoning by *equal* hours, was probably adopted between the 13th to the beginning of the 16th century. The change would necessarily follow the introduction of striking clocks in the earlier part of the fourteenth century, for, however imperfect these were, the hours they marked would be of the same length in summer and in winter, and the discrepancy between these equal hours and the temporary hours of the sundial would soon be too important to be overlooked. Now, we know that a striking clock was put up in Milan in 1336, and we

FIG. 5.—EARLY SUNDIALS WITH TIDE LINES (LINES WITH CROSSES) MARKING THE FOUR TIDES INTO WHICH THE SAXONS DIVIDED THEIR DAY. Left Earliest English Sundial Bewcastle Cross. Right Saxon Sundial at Dagingworth, Gloucestershire.

adapted for use as a moon-dial when the moon's age is known, may be seen in Queens' college, Cambridge.

During the 17th century drilling was a special branch of education. The great work of Clavius, a quarto volume of 800 pages, was published in 1612, and may be considered to contain all that was known at that time.

In the 18th century clocks and watches began to supersede sundials, and the latter gradually fell into disuse, except dials in a garden or in remote country districts, where the old dial on the

FIG. 6.—DRAKE'S PORTABLE DIAL BY HUMPHREY COLE, A.D. 1569. The Equatorial Dial is set for latitude by the quadrant and in the meridian by the magnetic compass. The instrument includes a tide table, a nocturnal, a diagram of planetary aspects and a circumferenter.

church tower still serves as an occasional check on the modern clock by its side.

General Principles.—The daily and the annual motions of the earth are the elementary astronomical facts on which dialling is founded. That the earth turns upon its axis uniformly from west to east in 24 hours and that it is carried round the sun in one year at a nearly uniform rate is the correct way of expressing these facts. But the effect will be precisely the same, and it will suit our purpose better and make our explanations easier, if we adopt the ideas of the ancients of which our senses furnish apparent confirmation, and assume the earth to be fixed. Then, the sun and

stars revolve round the earth's axis uniformly from east to west once a day—the sun lagging a little behind the stars, making its day some four minutes longer—so that at the end of the year it finds itself again in the same place, having made a complete revolution of the heavens relatively to the stars from west to east.

The fixed axis about which all these bodies revolve daily is a line through the earth's centre, but the radius of the earth is so small, compared with the enormous distance of the sun, that, if we draw a parallel axis through any point of the earth's surface, we may safely look on that as being the axis of the celestial motion. The error in the case of the sun would not, at its maximum, that is, at 6 A.M. and 6 P.M., exceed half a second of time, and at noon would vanish. An axis so drawn is in the plane of the meridian, it points to the pole, and its elevation is equal to the latitude of the place.

The diurnal motion of the stars is strictly uniform, and so would that of the sun be if the daily retardation of about four minutes, spoken of above, were always the same. But this is constantly altering, so that the time, as measured by the sun's motion, and also consequently as measured by a sundial, does not move on at a strictly uniform pace. This irregularity, which is slight, would be of little consequence in the ordinary affairs of life, but clocks and watches being mechanical measures of time could not, except by extreme complication, be made to follow it.

A clock is constructed to mark uniform time in such wise that the length of the clock day shall be the average of all the solar days in the year. Four times a year the clock and the sundial agree exactly, but the sundial, now going a little slower, now a little faster, will be sometimes behind, sometimes before the clock—the greatest accumulated difference being about 16 minutes for a few days in November. The four days on which the two agree are April 15, June 15, Sept 1 and Dec 24.

Clock time is called *mean time*, that marked by the sundial is called *apparent time*, and the difference between them is the *equation of time*. It is given in most calendars and Almanacs frequently under the heading 'clock slow' or 'clock fast.' When the time by the sundial is known, the equation of time will at once enable us to obtain the corresponding clock time, or vice versa.

The general principles of dialling will now be readily understood. The problem before us is the following—A rod or style, as it is called, being firmly fixed in a direction parallel to the earth's axis, we have to find how and where hour-lines of reference must be traced on some fixed surface behind the style so that when the shadow of the style falls on a certain one of these lines we may know that at the moment it is solar noon—that is, that the plane through the style and through the sun then coincides with the meridian, again, that when the shadow reaches the next line of reference it is 1 o'clock by solar time or which comes to the same thing, that the above plane through the style and through the sun has just turned through the 24th part of a complete revolution, and so on for the subsequent hours, the

hours before noon being indicated in a similar manner.

The position of an intended sundial having been selected, the surface must be prepared, if necessary, to receive the hour lines. The style must be accurately fixed in the meridian plane, and must make an angle with the horizon equal to the latitude of the place. The latter condition will offer no difficulty, but the exact determination of the meridian plane which passes through the point where the style is fixed to the surface is not so simple.

The position of the XII o'clock line is the most important to determine accurately, since all the others are usually made to depend on this one. We cannot trace it correctly on the dial until

the style has been itself accurately fixed in its proper place. When that is done the XII o'clock line will be found by the intersection of the dial surface with the vertical plane which contains the style, and the most simple way of drawing it on the dial will be by suspending a plummet from some point of the style whence it may hang freely, and waiting until the shadows of both style and plummet coincide on the dial. This single shadow will be the XII o'clock line. In one class of dials, namely, all the vertical ones, the XII o'clock line is simply the vertical line from the centre, it can, therefore, at once be traced on the dial face by using a fine plumbline. The XII o'clock line being traced, the easiest and most accurate method of tracing the other hour lines would, at the present day when good watches are common, be marking where the shadow of the style falls, when 1, 2, 3, etc., hours have elapsed since noon, and the next morning by the same means the forenoon hour lines could be traced, and in the same manner the hours might be subdivided into halves and quarters, or even into minutes. But formerly, when watches did not exist, the tracing of the I, II, III, etc., o'clock lines was done by calculating the angle each would make with the XII o'clock line.

Dials received different names according to their position—*Horizontal dials*, when traced on a horizontal plane, *Vertical dials*, when on a vertical plane facing one of the cardinal points, *Vertical declining dials*, when on a vertical plane not facing a cardinal point. *Inclining dials*, when traced on planes neither vertical nor horizontal (these were further distinguished as *reclining* when leaning backwards from an observer *proclining* when leaning forwards). *Egnatorial dials*, when the plane is at right angles to the earth's axis, etc.

There are many early vertical south dials of great archaeological interest on the walls of English churches. The simplest of all are the Anglo-Saxon dials, in which the day is divided into four tides of three hours each. A good example may be seen at Daglingworth. In the dial on Bury St. Edmunds in the 7th century, hour lines have been intercalated between the early use lines, which are marked with crosses. Upon church walls of the Early English period scratch dials or mass dials of various types are often found. In their simplest form they consist of a few hour lines radiating from a central hole in which a wooden style would have been inserted. A vertical noon line is always present. Lines at right angles to it would have been for 6 A.M. and 6 P.M., and one half way between the former and the noon line would have been for 9 A.M. Occasionally a circle of holes takes the place of the hour lines.

In the commonest type of horizontal dials the dial plate is of metal, as well as the vertical piece upon it, and they may be purchased ready for placing on the pedestal, the dial with all the

The artist has shown all the months of the year on one side of the cylinder. In modern examples of the dial used in the Pyramids the lines for 6 months only would appear on one side.

hour lines traced on it and the style plate firmly fastened in its proper position, or cast in the same piece with the dial plate.

When placing it on the pedestal care must be taken that the dial be perfectly horizontal and accurately oriented. The levelling will be done with a spirit level and the orientation will be best effected either in the forenoon or in the afternoon by turning the dial plate till the time given by the shadow (making the small

FIG 10—THE CAPUCHIN. A FLAT ALTITUDE DIAL OF THE 17TH CENTURY. In use the end S of the plumb line SP is moved along a slot to the day of the month and the bead B' is shifted to the hour 12. The sights KK', at the upper edge are then pointed at the sun and the bead on the plumb line will show the hour. In Sir John Findlay's Collection.

correction mentioned above) agrees with a good watch whose error on solar time is known. It is, however, important to bear in mind that a dial, so built up beforehand, will have the angle at the base equal to the latitude of some selected place, such as London, and the hour lines will be drawn in directions calculated for the same latitude. Such a dial, therefore, could not be used near Edinburgh or Glasgow, although, it would, without appreciable error, be adapted to any place whose latitude did not differ more than 20 or 30 m from that of London.

Portable Dials were made generally of a small size, so as to be carried in the pocket, and these, so long as the sun shone, answered the purpose of a watch. The description of the portable dial has often been mixed up with that of the fixed dial, as if it had been merely a special case, and the same principle had been the basis of both, but although some are like the fixed dials, with the addition of some means for orientating the dial, others depend on the very irregularly varying zenith distance of the sun.

Portable dials fall into two main classes *Altitude Dials* and *Compass Dials*.

I Altitude Dials find the time from the altitude of the sun, allowance being made for the season of the year. An early example was the Roman *Hum* dial excavated at Herculaneum under the Vesuvian muds of the eruption of A.D. 79. It is marked with the months of July and August, and must therefore be more recent than 27 B.C. It was only serviceable in one latitude. A more useful type of altitude dial "for all climates," as Vitruvius describes it, is a Roman dial of about A.D. 250 in the Lewis Evans collection, which has adjustments both for the seasons and for latitude from 30° to 60°. Another form of altitude dial is known as the Shepherd's dial or Cylinder dial. The earliest description of them is by Hermannus Contractus (1013-1054), and they are still in use among the peasants in the Pyrenees.

In this type there is a horizontal gnomon and the hour lines are curves of the length of the shadow of this gnomon on a vertical surface, according to the hour and season. These curves are drawn either on a cylinder or a flat surface. The seasons are represented by vertical lines, and the gnomon is moved to the appropriate line, the dial being so placed that the shadow falls perpendicularly and the hour is read on the hour line.

A very neat and ingenious flat altitude dial on a *Card* is attributed to Ozanam to a Jesuit Father, De Saint Rigaud, but it

dates from the time of Regiomontanus. It was sometimes called the *capuchin*, from some fancied resemblance to a cowl thrown back.

Other altitude dials are the Quadrant dials, Ring dials, and Universal Ring dials. The Ring dial consists of a ring of brass that can be suspended by a small loop. A second, sliding ring within the first is drilled with a conical hole, with its apex towards the inside. When the sun's rays pass through this hole they make a spot of light upon the opposite inner surface of the ring, which is divided by hour lines. The time can thus be read off.

The sliding ring is for adjustment for the latitude of the place, and the hour lines run diagonally for correction for the season of the year.

In the Universal Astronomical Ring dial a metal ring represents

the meridian, and is suspended by a small ring and shackle adjustable for latitude. Fixed to the meridian ring, so that it will fold within it when not in use, is a second or equatorial ring, divided into the 24 hours. On the line of the polar axis is a flat metal plate with a longitudinal slot, in which slides a block with a pinhole in it. This being adjusted for the sun's declination by means of a scale on the plate, and the instrument suspended with its meridian circle in the meridian, the rays of the sun passing through the pinhole will fall on the hour of the

FIG 13—THE OLDEST KNOWN COMPASS DIAL. A.D. 1451. This was probably made at Nuremberg, and is now at Innsbruck.

II Compass Dials made their appearance in the 15th century, some 150 years after the description of the magnetic compass by Peter Peregrinus. In their simplest form they consist merely of a horizontal dial and a compass; but to these numerous acces-

of everyday life involving common character types. Although Plato knew and admired the Sicilian myths, the form of philosophical dialogue that he had perfected by 400 B.C. was sufficiently original to be an independent literary creation. With due attention to characterization and the dramatic situation from which the discussion arises, it develops dialectically the main tenets of Platonic philosophy. To Lucian in the 2nd century A.D., the dialogue owes a new tone and function. His influential *Dialogues of the Dead* with their coolly satirical tone inspired innumerable imitations in England and France during the 17th and 18th centuries, of these, the best known are works of the same name by Bernard de Fontenelle (1683) and François Fenelon (1712). The revival of interest in Plato during the Renaissance encouraged numerous imitations and adaptations of the Platonic dialogue. In Spain, Juan de Valdes used it to discuss problems of philology (1533) and Vincenzo Carducci, theories of painting (1633). In Italy, dialogues on the Platonic model were written by Torquato Tasso (1580), Giordano Bruno (1584) and Galileo Galilei (1632). The Renaissance also adapted the dialogue form to uses unsuspected by either Plato or Lucian. It was widely used in the teaching of languages by the direct method.

In the 16th and 17th centuries, dialogue lent itself easily and frequently to the presentation of controversial religious, political and economic ideas. Bishop George Berkeley's *Dialogues Between Hylas and Philonous* (1713) are perhaps the best of the English imitations of Plato.

The best known 19th-century examples of the form are Walter Savage Landor's *Imaginary Conversations* (1824-29), sensitive recreations of historical personages. G. Lowes Dickinson's *A Modern Symposium* (1905) and André Gide's *Imaginary Interwoven* (1944) illustrate the continued appeal of this ancient form in the 20th century.

(F. B. M.)

DIALYSIS (Gr. *di-*, through, *lysis*, to loosen), a process first employed by Thomas Graham (1861) to separate colloidal particles from those of ionic or small molecular dimensions (crystalloids). If such a mixture is placed in a sack made of parchment, collodion or cellophane, or in a drum provided with a bottom of such material, and suspended in water, the ions and small molecules pass through the membrane, leaving the colloidal particles in the drum or sack.

The process is a slow one and may, in some cases, be accelerated by heating or by an electric field (electrodialysis). The separation depends upon the difference in size between the colloidal and crystalline constituents, the membrane having pores of intermediate size. (See COLLOIDS.) (A. E. A.)

DIAMAGNETISM Some substances, like iron, are attracted strongly by the pole of a magnet and are said to be ferromagnetic, others are attracted weakly and are paramagnetic, still others are repelled and these are called diamagnetic. In 1778 S. J. Brugmans observed for the first time the repulsive action of bismuth and antimony in the strong nonuniform field of an electromagnet.

In 1845 and the following years Michael Faraday examined a great many substances and found many of the elements and most of the compounds to be diamagnetic, it was he who first used the words diamagnetic and paramagnetic. The most highly diamagnetic substance known is bismuth, in a nonuniform field its repulsive force is measured by its susceptibility, -0.00013 , a value very small compared to the (paramagnetic) susceptibility often found in iron, $+500$. Diamagnetic materials are composed of atoms that have completed electron shells (see ATOM) and no permanent magnetic moments. The electrons circulating in such atoms are either speeded up or slowed down by the application of a field, and the resulting change in magnetization, the "induced" moment, opposes the field. This opposition of the magnetic field and the induced magnetism is characteristic of diamagnetism (See MAGNETISM.) (R. M. B.)

DIAMANTE, FRA, Italian fresco painter of the 15th century was a Carmelite friar, a member of the Florentine community of that order. He was the principal assistant of Fra Filippo Lippi in the execution of frescoes at the cathedrals of Prato and of Spoleto, which Diamante completed after his master's death in 1469. Fra Filippo left a young son in the care of Diamante (see LIPPI).

DIAMANTE, JUAN BAUTISTA (1640?-1684?), Spanish dramatist, was born at Castillo about 1640, entered the army and began writing for the stage in 1657. Like many other Spanish dramatists of his time, Diamante is deficient in originality and his style is riddled with affectations, *La Desgraciada Raquel*, which was long considered to be his best play, is really Mira de Amescua's *Judith de Toledo* under another title, and the earliest of Diamante's surviving pieces, *El Honrador de su padre* (1658), is virtually a free translation of Corneille's *Le Cid*. Diamante was the introducer of French dramatic methods into Spain.

DIAMANTINA (formerly called Tejuco), a mining town of the state of Minas Gerais, Brazil, in the northeastern part of the state, 3,710 ft. above sea level. Urban population of the *município* (1950) 57,550. Diamantina is built partly on a steep hillside overlooking a small tributary of the Jequitinhonha river (where diamond washing was once carried on), and partly on the level plain above.

The town is roughly but substantially built, with broad streets and large squares. It is the seat of a bishopric, with an episcopal seminary, and has many churches, a lunatic asylum, a theatre, military barracks, hospitals and a secondary school. There are several small manufactures including cotton weaving, tanning and shoemaking, and diamond cutting is carried on. Diamantina is the commercial centre of an extensive region, and is noted for its wealth. The present name of the town was assumed (instead of Tejuco) in 1838, when it was made a *cidade*. (See MINAS GERAIS.)

DIAMANTINO, a small town of the state of Mato Grosso, Brazil, near the Diamantina river, about 6 m. above its junction with the Paraguay, in $14^{\circ} 44' 31''$ S., $56^{\circ} 8' 30''$ W.

The population of the municipality in 1950 was 6,285, mostly Indians. It stands in a broken sterile region 1,817 ft. above sea level and at the foot of the great Mato Grosso plateau. The first mining settlements date from 1730, when gold was found in the vicinity. On the discovery of diamonds in 1746 the settlement drew a large population and for a time was very prosperous.

The mines failed to meet expectations, however, and the population declined, it grew slowly after 1880. Ipeacuanha and vanilla beans are the principal articles of export.

DIAMETER, in geometry, a straight line passing through the centre of a conic section and terminated by the curve (from the Gr. *di-*, through, *metron*, measure). The principal diameters of the ellipse and hyperbola coincide with the axes and are at right angles, conjugate diameters are such that each bisects chords parallel to the other.

The diameter of a quadric surface is a line at the extremities of which the tangent planes are parallel. Newton defined the diameter of a curve of any order as the locus of the centres of the mean distances of the points of intersection of a system of parallel chords with the curve.

The word is also used as a unit of linear measurement of magnetizing power.

In architecture, the term is used with reference to the lower part of the shaft of a column. It is employed by Vitruvius (iii, 2) to determine the height of a column, and it is generally the custom to fix the lower diameter of the shaft by the height required and the order employed.

Thus the diameter of the Roman Doric should be about one-eighth of the height, that of the Ionic one-ninth and of the Corinthian one-tenth. (See CIRCLE, CONIC SECTION, ELLIPSE, HYPERBOLA, ORDER, PARABOLA.)

DIAMOND, mineral universally recognized as chief among precious stones, it is the hardest, the most impishable and also the most brilliant of minerals. These qualities alone have made it

supreme as a jewel since early times, and yet the real brilliancy of the stone is not displayed until it has been faceted by the art of the lapidary (*q.v.*) and this was scarcely developed before the year 1746. The consummate hardness of the diamond, in spite of its high price, has made it most useful for purposes of grinding, polishing and drilling. Numerous attempts have been made to manufacture the diamond by artificial means, and these attempts have a high scientific interest on account of the mystery which surrounds the natural origin of this remarkable mineral. Its physical and chemical properties have been the subject of much study, and have a special interest in view of the extraordinary difference between the physical characters of the diamond and those of graphite (blacklead) or charcoal, with which it is chemically identical, and into which it can be converted by the action of heat or electricity.

The name *Adamas* "the invincible," was probably applied by the Greeks to hard metals, and thence to corundum (emery) and other hard stones. According to Charles William King, the first undoubted application of the name to the diamond is found in Manilius (A.D. 16)—*Sic Adamas, punctum lapidis, pretiosior auro*,—and Pliny (A.D. 100) speaks of the rarity of the stone, "the most valuable of gems, known only to kings." Pliny described six varieties, among which the Indian, having six pointed angles, and also resembling two pyramids (*turbines*, whip tops) placed base to base, may probably be identified as the ordinary octahedral crystal (fig. 1). The diamond (*Yahalom*) in the breastplate of the high priest (Ex xxxix. 11) was certainly some other stone, for it bore the name of a tribe, and methods of engraving the true diamond cannot have been known so early. The stone can hardly have become familiar to the Romans until introduced from India, where it was probably mined at a very early period. But one or other of the remaining varieties mentioned by Pliny (the Macedonian, the Arabian, the Cyprian, etc.) may be the true diamond, which was in great request for the tool of the gem engraver. Later Roman authors mentioned various rivers in India as yielding the *Adamas* among their sands. The name *Adamas* became corrupted into the forms *adamant*, *diamant*, *diamond*, but the same word, owing to a mediaeval misinterpretation which derived it from *adamas* (compare the French word *amant*), was also applied to the lodestone.

Scientific Characters.—Diamond is almost always found in single crystals, which show no signs of previous attachment to any matrix, the stones were, until the discovery of the South African mines, almost entirely derived from sands or gravel, but owing to the largeness of the mineral it is rarely, if ever, water-worn, and the crystals are often very perfect. The crystals are large to the cubic system, generally assuming the form of the octahedron (fig. 1) but they may, in accordance with the principles of crystallography, also occur in other forms symmetrically derived from the octahedron, e.g. the cube, the rhombic figure known as the rhombic dodecahedron (fig. 2), or the 48-faced figure known as the hexakis octahedron (fig. 3), or in combinations of these. The octahedron faces are usually smooth, most of the other faces are rounded (fig. 4). The cube faces are rough with protruding points. The cube is sometimes found in Brazil, but is very rare among the South African stones, and the dodecahedron is perhaps more common in Brazil than elsewhere. The crystals are sometimes tetrahedral in aspect. There are also "twins" of diamond in which two octahedra (fig. 5) are united by contact along a surface parallel to an octahedron face, sometimes they interpenetrate. They are generally first ended along the prism of union. The crystals often display triangular markings, either elevated or pits upon the octahedron faces (fig. 6). They have

FIGS 1-4—DIAMOND CRYSTALS. From left to right octahedron eight faced, rhombic dodecahedron 12 faced, hexakis octahedron, 48 faced and rounded.

FIG 5—TWIN DIAMOND SHOWING TWO OCTAHEDRA JOINED ALONG A SURFACE PARALLEL TO AN OCTAHEDRON FACE.

probably been produced by the action of some solvent. The actual arrangement of the carbon atoms in the crystal has now been ascertained by means of X-ray investigations.

Diamond possesses a brilliant "adamantine" lustre, but this tends to be greasy on the surface of the natural stones and gives the rounded crystals somewhat the appearance of drops of gum. Absolutely colourless stones are not so common as cloudy and faintly coloured specimens, the usual tints are grey, brown, yellow or white, and as rarities, red, green, blue and black stones have been found. The colour can sometimes be removed or changed at a high temperature, but generally returns on cooling. It is therefore more probably due to metallic oxides than to hydrocarbons.

FIG 6—DIAMOND CRYSTAL OCTAHEDRON SHOWING TRIANGULAR MARKINGS.

Sir William Crookes has, however, changed a pale yellow diamond to a bluish green colour by keeping it embedded in radium bromide for 11 weeks. Diamond may break with a conchoidal fracture, but the crystals always cleave readily along planes parallel to the octahedron faces, of this property the diamond cutters avail themselves when reducing the stone to the most convenient form for cutting, a sawing process, however, has now been introduced, which is preferable to that of cleavage. It is the hardest known substance (though tantalum, or an alloy of tantalum, now competes with it) and is chosen as ten in the mineralogist's scale of hardness, the Borneo stones are said to be harder than others. The specific gravity ranges from 3.56 to 3.59, generally about 3.52. The coefficient of expansion increases very rapidly above 750°, and diminishes very rapidly at low temperatures, the maximum density is attained when a temperature of about -42° Centigrade is reached.

Brilliance and "Fire."—The very high refractive power (index = 2.417 for sodium light) gives the stone its extraordinary brilliancy, for light incident within a diamond at a greater angle than 24½° is reflected back into the stone instead of passing through it, the corresponding angle for glass is 48°. The very high dispersion (index for red light = 2.409, for blue light = 2.460) gives it the wonderful "fire"—or display of spectral colours. Unlike other cubic crystals, diamond experiences a diminution of refractive index with increase of temperature. It is very transparent for Röntgen rays, whereas paste imitations are opaque. It is a good conductor of heat, and therefore feels colder to the touch than glass and imitation stones. The diamond has also a somewhat greasy feel. The specific heat increases rapidly with rising temperature up to 660° C, and then more slowly. Crystals belonging to the cubic system should not be birefringent unless strained; diamond often displays a double refraction particularly in the neighbourhood of inclusions, both liquid and solid, this is probably due to strain, and the spontaneous explosion of diamonds has often been observed. Diamond differs from graphite in being a bad conductor of electricity, it becomes positively electric by friction. The electrical resistance is about that of ordinary glass, and is diminished by oxidation during exposure to Röntgen rays, the dielectric constant (10) is greater than that which should correspond to the specific gravity.

The phosphorescence produced by friction has been known since the time of Robert Boyle (1663), the diamond becomes luminous in a dark room after exposure to "night air" or in the vacuum of radium, and many stones phosphoresce beautifully (generally with pale green light) when subjected to the electric discharge in a vacuum tube. Some diamonds are more phosphorescent than others, and of different tints of colour may display different tints. The combustibility of the diamond was predicted by Sir Isaac Newton on account of its high refractive power; it was first established experimentally by the Florentine academy in 1694. If oxygen or air at 1000° burns a diamond, and only continues to do so if maintained at a high temperature, but in the absence of oxidizing agent it may be raised to a much higher temperature. It is, however, intusible at the temperature of the electric arc. It becomes blackened superficially by exposure to the combustion of diamond were made by Smuts and Tennant (1797) and Sir Humphry Davy (1816), with the object of proving that

it is pure carbon. Diamond is insoluble in acid and alkalis, but is oxidized on heating with potassium bichromate and sulphuric acid.

Uses of the Diamond.—The use of the diamond for other purposes than jewellery depends upon its extreme hardness. It has always been the only material used for cutting or engraving the diamond itself. The employment of powdered bort (*qv*) and the lapidary's wheel for faceting diamonds was introduced by L. von Berquen of Bruges in 1476. Diamonds are now employed not only for faceting precious stones, but also for cutting and drilling glass, porcelain, etc., for fine engraving such as scales, in dentistry for drilling, as a turning tool for electric light carbons, hard rubber, etc., and occasionally for finishing accurate turning work. It is also used for bearings in watches and electric meters. The best glaziers' diamonds are chosen from crystals such that a natural curved edge can be used. For rock drills, and revolving saws for stone cutting, either diamond, bort or carbonado (*qv*) is employed, set in steel tubes, discs or bands. Rock drilling is the most important industrial application, and for this owing to its freedom from cleavage, the carbonado is more highly prized than diamond. Another application of the diamond is for wire drawing, a hole tapering towards the centre is drilled through a diamond, and the metal is drawn through this. No other tool is so durable, or gives such uniform thickness of wire.

Distribution and Mining.—The most important localities for diamonds have been (1) India, where they were mined from the earliest times till the close of the 19th century, (2) South America, where they have been mined since the middle of the 18th century, and (3) South Africa, to which almost the whole of the diamond-mining industry has been transferred since 1870.

Indian Diamonds.—The diamond is here found in ancient sandstones and conglomerates, and in the river gravels and sands derived from them. The sandstones and conglomerates belong to the Vindhyan formation and overlie the old crystalline rocks. The diamantiferous beds are well defined, often not more than 1 ft. in thickness, and contain pebbles of quartzite, jasper, sandstone, slate, etc. The mines fall into five groups situated on the eastern side of the Deccan plateau. The mining has always been carried on by natives of low caste, and by primitive methods which do not differ much from those described by the French merchant, Jean Baptiste Tavernier (1605-89), who paid a prolonged visit to most of the mines between 1638 and 1665 as a dealer in precious stones.

At some of the Indian localities spasmodic mining has been carried on at different periods for centuries, at some the work which had been long abandoned was revived in recent times, at others it has long been abandoned altogether. Many of the large stones of antiquity were probably found in the Kollur group, where Tavernier found 60,000 workers in 1645 (?), the mines, according to native accounts, having been discovered about 100 years previously. Golconda was the fortress and the market for the diamond industry at this group of mines, and so gave its name to them. Very few Indian diamonds now find their way out of the country, and so far as the world's supply is concerned, Indian mining of diamonds may be considered extinct. The first blow to this industry was the discovery of the Brazilian mines in Minas Geras and Baía.

Brazilian Diamonds.—Diamonds were found about 1725 at Tejuco (now Diamantina) in Minas Geras, and the mining became important about 1740. The Rio Abaeté district was worked on a considerable scale between 1785 and 1807, but is now abandoned. Diamantina is at present the most important district, it occupies a mountainous plateau, and the diamonds are found both on the plateau and in the river valleys below it. The mountains consist here of ancient laminated micaceous quartzite, which is in parts a flinty sandstone known as itacolumite, and in parts a conglomerate. The diamond is found under three conditions: (1) in the gravels of the present rivers, embedded in a ferruginous clay cemented conglomerate known as *cascalho*, (2) in terraces occupying higher levels, (3) in plateau deposits embedded in the red clay which cements the larger blocks. The terraces are probably a first concentration of the plateau material by the old rivers, and the *cascalho* a second concentration by the

modern rivers.

In recent years the Minas Geras mines have been rivalled by the yield in Baía. The diamond here occurs in river gravels and sands associated with the same minerals as in Minas Geras, since 1844 the richest mines have been worked in the Serra de Cincura, where the mountains are intersected by the River Para-guassu and its tributaries, it is said that there were as many as 20,000 miners working here in 1845, and it was estimated that 54,000 carats were produced in Baía in 1858. But the enormous development of the South African mines, which in 1906 supplied about 90% of the world's produce, has thrown the Brazilian production into the shade.

African Diamonds.—The first discovery was made in 1867 by Dr W. G. Atherstone, who identified as diamond a pebble obtained from a child in a farm on the banks of the Orange river and brought by a trader to Grahamstown, it was bought for £500 and displayed in the Paris Exhibition of that year. In 1869 a stone weighing 83½ carats was found near the Orange river, this was purchased by the earl of Dudley for £25,000 and became famous as the "Star of South Africa." A rush of prospectors at once took place to the banks of the Orange and Vaal rivers, and resulted in considerable discoveries, so that in 1870 there was a mining camp of no less than 10,000 persons on the "River Diggings." In the River Diggings the mining was carried on in the coarse river gravels, and by the methods of the Brazilian negroes and of gold placer miners. A diggers' committee limited the size of claims to 50 ft. square, with free access to the river bank, the gravel and sand were washed in cradles provided with screens of perforated metal, and the concentrates were sorted by hand on tables by means of an iron scraper.

But towards the close of 1870 stones were found at Jagersfontein and at Dutoitspan, far from the Vaal river, and led to a second great rush of prospectors, especially to Dutoitspan, and in 1871 to what is now the Kimberley mine in the neighbourhood of the latter. At each of these spots the diamantiferous area was a roughly circular patch of considerable size, and in some it occupied the position of one of those depressions or "pans" so frequent in South Africa. These "dry diggings" were therefore at first supposed to be alluvial in origin like the river gravels, but it was soon discovered that, below the red surface soil and the underlying calcareous deposit, diamonds were also found in a layer of yellowish clay about 50 ft. thick known as "yellow ground." Below this again was a hard bluish-green serpentine rock which was at first supposed to be barren bed rock, but this also contained the precious stone, and has become famous, under the name of "blue ground," as the matrix of the South African diamonds. The yellow ground is merely decomposed blue ground. In the Kimberley district five of these round patches of blue ground were found within an area little more than 3 m. in diameter, that at Kimberley occupying 12 ac., that at Dutoitspan 23 acres. There were soon 50,000 workers on this field, the canvas camp was replaced by a town of brick and iron surrounded by the wooden huts of the natives, and Kimberley became an important centre.

It was soon found that each mine was in reality a huge vertical funnel or crater descending to an unknown depth, and filled with diamantiferous blue ground. At first each claim was an independent pit 25 ft. square sunk into the blue ground. The diamantiferous rock was hoisted by buckets and winches, and ladders were left across the pit to provide access to the claims. But the workings soon fell in, and ultimately haulage from the claims could only be provided by means of a vast system of vertical ropes extending from a triple staging of windlasses erected round the entire edge of the mine, which had by this time become a huge open pit, the ropes from the upper windlasses extended to the centre and those from the lower tier to the sides of the pit, covering the whole mass like a gigantic collier or lute steel ropes. The buckets of blue ground were hauled up these ropes by means of horse whips, and in 1875 steam winding engines began to be employed. By this time also improved methods in the treatment of the blue ground were introduced. It was carried off in carts to open spaces, where an exposure of some weeks to the air was found to pulverize

the hard rock far more efficiently than the old method of crushing with mallets. The placer miner's cradle and rocking trough were replaced by puddling troughs stirred by a revolving comb worked by horse power, reservoirs were constructed for the scanty water-supply, bucket elevators were introduced to carry away the tailings, and the natives were confined in compounds. For these improvements co operation was necessary, the better claims, which in 1872 had risen from £100 to more than £4,000 in value, began to be consolidated, and a mining board was introduced.

In a very few years, however, the open pit mining was rendered impossible by the mud rushes, by the falls of the masses of barren rock known as "rief" which were left standing in the mine and by landslips from the sides, so that in 1883, when the pit had reached a depth of about 400 ft., mining in the Kimberley crater had become almost impossible. By 1889, in the whole group of mines, Kimberley, Dutoitspan, De Beers and Bultfontein, open pit working was practically abandoned. Meanwhile mining below the bottom of the pits by means of shafts and underground tunnels had been commenced, but the full development of modern methods dates from the year 1889 when Cecil Rhodes and Alfred Beit, who had already secured control of the De Beers mine, acquired also the control of the Kimberley mine, and shortly afterwards consolidated the entire group in the hands of the De Beers Company (see KIMBERLEY).

The scene of native mining was now transferred from the open pit to underground tunnels, the vast network of wire ropes disappeared, and with it the cosmopolitan crowd of busy miners working like ants at the bottom of the pit. In place of all this, the visitor to Kimberley encounters at the edge of the town only a huge crater, silent and apparently deserted, with no visible sign of the great mining operations which are conducted far below the surface.

A vertical shaft through the basalt, shale and granite is sunk in the vicinity of the mine, and from this horizontal tunnels are driven into the pipe at different levels separated by intervals of 40 feet. Through the blue ground itself on each level a series of parallel tunnels about 120 ft. apart are driven to the opposite side of the pipe, and at right angles to these, and 36 ft. apart, another series of tunnels. When the tunnels reach the side of the mine

FIG. 7.—SECTION OF THE KIMBERLEY DIAMOND MINE IN SOUTH AFRICA.

From vertical shafts sunk near the mine, horizontal tunnels are driven into the pipe of blue ground, at levels 40 ft. apart the excavated material being brought up through the rock shafts.

they are opened upwards and sides are allowed to form a large chamber, and the overlying mass of blue ground and debris is allowed to settle down and fill up the gallery. On each level of this process is carried somewhat farther back than on the level below (fig. 7), material is thus continually withdrawn from one side of the mine and extracted by means of the rock shaft on the opposite side, while the superincumbent debris is continually sinking and is allowed to fall deeper on the side farthest from the shaft as the blue ground is withdrawn from beneath it. In 1905 the main shaft had been sunk to a depth of 1,600 ft. at the Kimberley mine.

For the extraction and treatment of the blue ground the De Beers Company in its great winding and washing plant employs labour saving machinery on a gigantic scale. The ground is transferred in trucks to the shaft where it is automatically tipped into skips holding 96 cu. ft. (six truck loads), these are rapidly hoisted to the surface, where their contents are automatically dumped into side tipping trucks, and these in turn are drawn away in a continual procession by an endless wire rope along the tram lines leading to the vast "distributing floors." These are open trunks upon which the blue ground is spread out and left exposed to sun and rain until it crumbles and disintegrates, the process being hastened by harrowing with steam ploughs, this may require a period of three or six months, or even a year. The stock of blue ground on the floors at one time in 1905 was nearly 4,500,000 loads. The disintegrated ground is then brought back in the trucks and fed through perforated cylinders into the washing pans, the "hard blue" ground which has resisted disintegration on the floors, and the lumps which are too big to pass the cylindrical sieves, are crushed before going to the pans. These are shallow cylindrical troughs containing muddy water in which the diamonds and other heavy minerals (concentrates) are swept to the rim by revolving toothed arms, while the lighter stuff escapes near the centre of the pan. The concentrates are then passed over sloping tables (pulsator) and shaken to and fro under a stream of water which effects a second concentration of the heaviest material.

Until recently the final separation of the diamond from the concentrates was made by hand picking, but even this has now been replaced by machinery, owing to the remarkable discovery that a greased surface will hold a diamond while allowing the other heavy minerals to pass over it. The concentrates are washed down a sloping table of corrugated iron which is smeared with grease and it is found that practically all the diamonds adhere to the table, and the other minerals are washed away. At the large and important Premier mine in the Transvaal the Elmore process, used in British Columbia and in Wales for the separation of metallic ores, has been also introduced. In the Elmore process oil is employed to float off the materials which adhere to it, while the other materials remain in the water, the oil being separated from the water by centrifugal action.

In all the South African mines the diamonds are not only crystals of various weights from fractions of a carat to 150 carats, but also occur as microscopic crystals disseminated through the blue ground. In spite of this, however, the average yield in the profitable mines is only from 0.2 carat to 0.6 carat per load of 1,600 lb. or on an average about 14 grs. per ton. The annual output of diamonds from the De Beers mines was valued in 1906 at nearly £5,000,000, the value per carat ranging from about 35 to 70 shillings.

Pipes similar to those which surround the Kimberley have been found in other parts of South Africa. One of the best known is that of Jagersfontein, which was really the first of the dry diggings (discovered in 1870). This large mine is near Fauresmuth and 80 m. to the south of Kimberley. In 1905 the year's production from the Orange River Colony mines was more than 320,000 carats, valued at £938,000. But by far the largest of all the pipes hitherto discovered is the Premier mine in the Transvaal, about 300 m. to the east of Kimberley. This was discovered in 1902 and occupies an area of about 75 acres. Comparatively few of the pipes which have been discovered are at all rich in diamonds, and many are quite barren, some are filled with "hard blue" which, even if diamantiferous, may be too expensive to work.

The most competent South African geologists believe all these pipes to be connected with volcanic outbursts which occurred over the whole of South Africa during the Cretaceous period (after the deposition of the Stormberg beds) and drilled the continuous cracks through all the later formations. It is a great part of Cape Colony have been discovered what are probably similar pipes filled with conglomerates, breccias and tuffs, and some with basalt lavas.

The River Diggings on the Vaal river are still worked upon a small scale but the production from this source is so limited that they are of little account in comparison with the mines in the blue

JONKER DIAMOND NUMBER ONE

Colour photograph of Jonker Diamond Number One which is mounted in a platinum necklace set with baguette diamonds. The stone is the largest emerald cut diamond in existence, with a weight of 125.35 carats and is shown in actual size. It has a magnificent bluish-white colour, and is expertly cut to bring out the maximum of its brilliancy and fire. Jonker Diamond Number One is the largest of 12 stones cut by Lazare Kaplan & Sons, Inc. from the 726 carat rough Jonker diamond, which was found in 1934 at Elandsfontein, Pretoria by Jacobus Jonker, an impoverished South African prospector.

ground. The stones, however, are good, since they differ some what from the Kimberley crystals it is probable that they were not derived from the present pipes. Considerable finds of diamonds were reported in 1905 and 1906 from gravels at Somabula near Gwelo in Rhodesia. Diamonds have also been reported from kimberlite "pipes" in Rhodesia.

The South African output in 1926 was 3,000,000 carats. Diamonds have been found in considerable numbers in sand near Luderitz bay in South West Africa (1908), the output from this district in 1926 was 515,000 carats. The Congo has become an important source since the first discovery in 1903, the diamonds are found in alluvial deposits of the River Kasai and its affluents. The output in 1926 was 1,708,000 carats from Belgian Congo, and 150,000 carats from Angola. Other African localities are the Gold Coast and Tanganyika.

Other Localities—In addition to the South American localities mentioned above, small diamonds have also been mined since their discovery in 1890 on the River Mazaruni in British Guiana, and finds have been reported in the gold washings of Dutch Guiana. The output from British Guiana in 1926 was 182,000 carats. Borneo has possessed a diamond industry since the island was first settled by the Malays. Australia has yielded diamonds in alluvial deposits near Bathurst (where the first discovery was made in 1851) and at other places in New South Wales, in South Australia, in Victoria, in Western Australia, and in Queensland. In Tasmania also diamonds have been found in the Corinna gold fields. Europe has produced few diamonds. They have been found (1829) in the gold washings of Bissersk, and at other spots in the Urals. Also in Lapland and Siberia. In North America small stones have been found in alluvial deposits, mostly auriferous, in Georgia, North and South Carolina, Kentucky, Virginia, Tennessee, Wisconsin, California, Oregon and Indiana. Considerable interest attaches to the diamonds found in Wisconsin, Michigan and Ohio near the Great Lakes, for they are here found in the terminal moraines of the great glacial sheet which is supposed to have spread southwards from the region of Hudson bay.

Origin of the Diamond in Nature—It appears from the foregoing account that at most localities the diamond is found in alluvial deposits probably far from the place where it originated. The minerals associated with it do not afford much clue to the original conditions, they are mostly heavy minerals derived from the neighbouring rocks, in which the diamond itself has not been observed.

There are only a few localities at which the diamond has been supposed to occur in its original matrix—in India, in Minas Gerais, and at Inverell in New South Wales, but the evidence is certainly not sufficient to establish the presence of an original matrix. Finally there is the remarkable occurrence in the blue ground of the African pipes.

There has been much controversy concerning the nature and origin of the blue ground itself, and even granted that (as is generally believed) the blue ground is a much serpentinized volcanic breccia consisting originally of an olivine bronzite biotite rock (the so called kimberlite), it contains so many rounded and angular fragments of various rocks and minerals that it is difficult to say which of them may have belonged to the original rock, and whether any were formed *in situ*, or were brought up from below as inclusions. Carvill Lewis believed the blue ground to be true eruptive rock, and the carbon to have been derived from the bituminous shales of which it contains fragments. The Kimberley shales, which are penetrated by the De Beers group of pipes, were, however, certainly not the source of the carbon at the Premier (Transvaal) mine, for at this locality the shales do not exist. The view that the diamond may have crystallized out from solution in its present matrix receives some support from the experiments of W. Luzi, J. Friedlander, R. von Hasslinger and J. Wolff. E. Cohen, who regarded the pipes as of the nature of a mud volcano, and the blue ground as a kimberlite breccia altered by hydrothermal action, thought that the diamond and accompanying minerals had been brought up from deep seated crystalline schists. Other authors have sought the origin of the diamond in the action of the hydrated magnesian silicates on hydrocarbons derived from

bituminous schists, or in the decomposition of metallic carbides.

Of great scientific interest in this connection is the discovery of small diamonds in certain meteorites, both stones and irons, e.g., in the stone which fell at Novo Urei in Penza, Russia, in 1886, in a stone found at Carcote in Chile, and in the iron found at Cañon Diablo in Arizona. Graphitic carbon in cubic form (cliftonite) has also been found in certain meteoric "irons," and is now generally believed to be altered diamond. The claim by H. Moissan to have produced the diamond artificially, by allowing dissolved carbon to crystallize out at a high temperature and pressure from molten iron, coupled with the occurrence in meteoric iron, has led Sir William Crookes and others to conclude that the mineral may have been derived from deep seated iron containing carbon in solution (see the article GEMS, SYNTHETIC).

On the other hand, the occurrence in meteoric stones, and the experiments mentioned above, show that the diamond may also crystallize from a basic magma, capable of yielding some of the metallic oxides and ferro magnesian silicates, a magma, therefore, which is not devoid of oxygen. This is still more forcibly suggested by the remarkable eclogite boulder found in the blue ground of the Newlands mine, not far from the Vaal river, and described by T. G. Bonney. The boulder is a crystalline rock, and is studded with diamond crystals, a portion of it is preserved in the British Museum (Natural History). Similar boulders have also been found in the blue ground elsewhere. It seems therefore that a holo crystalline pyroxene garnet rock may be one source of the diamond found in blue ground. Some regard the eclogite boulders as derived from deep seated crystalline rocks, others as concretions in the blue ground. None of the inclusions in the diamond gives any clue to its origin.

Finally, then, both experiment and the natural occurrence in rocks and meteorites suggest that diamond may crystallize not only from iron but also from a basic silicate magma, possibly from various rocks consisting of basic silicates. The blue ground of South Africa may be the result of the serpentinization of several such rocks, and although now both brecciated and serpentinized some of these may have been the original matrix. A circumstance often mentioned in support of this view is the fact that the diamonds in one pipe generally differ somewhat in character from those of another, even though they be near neighbours.

History of Diamonds—All the famous diamonds of antiquity must have been Indian stones. The first author who described the Indian mines at all fully was the Portuguese Garcia de Orta (1565), who was physician to the viceroy of Goa. Before that time there were only legendary accounts like that of Sindbad's "Valley of the Diamonds," or the tale of the stones found in the brains of serpents. V. Ball thinks that the former legend originated in the Indian practice of sacrificing cattle to the evil spirits when a new mine is opened, birds of prey would naturally carry off the flesh, and might give rise to the tale of the eagles carrying diamonds adhering to the meat.

The following are some of the famous diamonds of the world.—A large stone found in the Golconda mines and said to have weighed 787 carats in the rough, before being cut by a Venetian lapidary, was seen in the treasury of Aurangzeb in 1665 by Tavernier, who estimated its weight after cutting as 280 (?) carats, and described it as a rounded rose-cut stone, tall on one side. The name *Great Mogul* has been frequently applied to this stone. Tavernier states that it was the famous stone given to Shah Jahan by the emir Jumla. The *Orloff*, stolen by a French soldier from the eye of an idol in a Brahmin temple, stolen again from him by a ship's captain, was bought by Prince Orloff for £90,000, and given to the empress Catharine II. It weighs 1942 carats, is of a somewhat yellow tinge, and is among the Russian Crown jewels. The *Koh-i-nor*, which was in 1739 in the possession of Nadir Shah, the Persian conqueror, and in 1813 in that of the raja of Lahore, passed into the hands of the East India Company and was by them presented to Queen Victoria in 1850. It then weighed 186 $\frac{1}{8}$ carats, but was recut in London by Amsterdam workmen, and now weighs 106 $\frac{1}{8}$ carats. There has been much discussion concerning the possibility of this stone and the Orloff being both fragments of the *Great Mogul*. The Mozul Baber in his memoirs (1526)

relates how in his conquest of India he captured at Agra the great stone weighing 8 miskals, or 320 carats, which may be equivalent to about 187 carats. The Koh-i-nor has been identified by some authors with this stone and by others with the stone seen by Tavernier. Tavernier, however, subsequently described and sketched the diamond which he saw as shaped like a bisected egg, quite different therefore from the Koh-i-nor. Nevil St. Mary's Maskeyne has shown reason for believing that the stone which Tavernier saw was really the Koh-i-nor, and that it is identical with the great diamond of Baber, and that the 280 carats of Tavernier is a misinterpretation on his part of the Indian weights. He suggests that the other and larger diamond of antiquity which was given to Shah Jahn may be one which is now in the treasury of Teheran, and that this is the true Great Mogul which was confused by Tavernier with the one he saw. (See Ball, Appendix I to Tavernier's *Travels* (1889), and Maskeyne, *Nature*, 1891, 44, p. 555.)

The *Regent* or *Pitt* diamond is a magnificent stone found in either India or Borneo, it weighed 410 carats and was bought for £20,400 by Pitt, the governor of Madras, it was subsequently, in 1717, bought for £80,000 (or, according to some authorities, £135,000) by the duke of Orleans, regent of France, it was reduced by cutting to 136½ carats, was stolen with the other Crown jewels during the Revolution, but was recovered and is still in France. The *Akbar Shah* was originally a stone of 116 carats with Arabic inscriptions engraved upon it, after being cut down to 71 carats it was bought by the gajwar of Baroda for £35,000. The *Nizam*, now in the possession of the nizam of Hyderabad, is supposed to weigh 177 carats, but it is only a portion of a stone which is said to have weighed 440 carats before it was broken. The *Sancy*, weighing 53½ carats, is said to have been successively the property of Charles the Bold, de Sancy, Queen Elizabeth, Henrietta Maria, Cardinal Mazarin, Louis XIV., to have been stolen with the *Pitt* during the French Revolution, and subsequently to have been the property of the king of Spain, Prince Demidoff and an Indian prince.

The *Great Table* a rectangular stone seen by Tavernier in 1642 at Golconda, was found by him to weigh 242½ carats, Maskeyne regards it as identical with the *Darya-i-nur*, which is also a rectangular stone weighing about 186 carats in the possession of the shah of Persia. Another stone, the *Taj-e-mah*, belonging to the shah, is a pale rose pear shaped stone and is said to weigh 146 carats.

Coloured Indian diamonds of large size are rare, the most famous are a beautiful blue brilliant, 57½ carats, cut from a stone weighing 112½ carats brought to Europe by Tavernier. It was stolen from the French Crown jewels with the *Regent* and was never recovered. The *Hope*, 44½ carats, has the same colour and is probably a portion of the missing stone. It was so-called as forming part of the collection of H. T. Hope bought for £18,000, and was sold again in 1906 (resold 1909). Two other blue diamonds are known weighing 13½ and 1½ carats, which may also be portions of the French diamond. The *Dresden Green*, one of the Saxony Crown jewels, 40 carats, has a fine apple green colour. The *Florentine*, 7½ carats, one of the Austrian Crown jewels, is a very pale yellow.

The most famous Brazilian stone was the *Star of the South*, found in 1853, when it weighed 354½ carats and was sold for £40,000, when cut it weighed 125 carats and was bought by the gajwar of Baroda for £80,000.

The **Largest Diamond**.—Many large stones have been found in South Africa, some are yellow but some are as colourless as the best Indian or Brazilian stones. The most famous are the following.—The *Star of South Africa*, or *Dudley*, mentioned above, 83½ carats rough, 46½ carats cut. The *St. Louis*, 288½ carats rough, 170 carats cut. Both these were found in the river diggings. The *Porter Rhodes* from Kimberley, of the finest water, weighed about 150 carats. The *Victoria*, 180 carats, was cut from an octahedron weighing 47½ carats, and was sold to the nizam of Hyderabad for £400,000. The *Tiffany*, a magnificent orange yellow stone, weighs 175½ carats cut. A yellowish octahedron found at De Beers weighed 428½ carats and yielded a brilliant of 278½ carats. Some of the finest and largest stones

have come from the Jagersfontein mine, one, the *Subter*, found in 1895, weighed 6½ carats in the rough and 239 carats when cut. Until 1905 the largest known diamond in the world was the *Excelsior*, found in 1893 at Jagersfontein by a native while loading a truck. It weighed 969½ carats, and was ultimately cut into ten stones weighing from 68 to 13 carats. But all previous records were surpassed in 1905 by the *Cullinan Diamond* more than three times the size of any known stone, which was found in the yellow ground at the newly discovered Premier mine in the Transvaal. It was purchased by the Transvaal Government in 1907 and presented to King Edward VII. It was sent to Amsterdam to be cut, and in 1908 was divided into nine large stones, the four largest weighing 516½ carats, 309½ carats, 92 carats and 62 carats respectively, and a number of small brilliants. The Jonker diamond, weighing 726 carats, was found in Elandsfontein in 1934, and was sold in May, 1935, to an American for about £150,000.

Diamonds are invariably weighed in carats. One English carat = 3.17 grains = 205½ grains. One metric carat (now nearly universally used) = 200 grains or 200 milligrams. (See *Carat*.)

DIAMOND MATCH COMPANY, THE, largest match company in the United States, was incorporated on December 26, 1930, under the laws of the State of Delaware, succeeding an Illinois corporation of the same name. It is engaged in the manufacture and the sale of matches, of match making machinery, of lumber and lumber products, and of other similar products.

The company holds a minority interest in the British Match Corporation Limited, of Great Britain and, with that firm and several others, in the F&B Match Company, Limited, located in Canada.

The properties of The Diamond Match Company and its subsidiaries include factories in nine different States of the Union, namely, New York, Maine, Massachusetts, Ohio, Wisconsin, New Jersey, Utah, Washington and California, they include also large timber tracts in the States of Maine, Georgia, Idaho, California and Washington, 64 lumber yards owned and operated in the Sacramento valley, California, and 22 in the New England States, and in addition a large card board plant in the State of Washington, and a match assembly plant at Springfield, Massachusetts.

The following figures give a comprehensive view of the extensive financial operation of the company: the total current assets as of December 31, 1939, were \$7,488,793.33, the total assets, \$34,380,747.16, the net working capital, \$20,050,559.14, the net income, \$2,136,770.49, the total surplus \$3,466,833.31.

The aggregate net income for the five years from 1935-1939, inclusive, was \$10,674,906.33 making an annual average, for that five year period of the sum of \$2,136,981.30.

The headquarters of the company are in the city of New York (W. W. H.)

DIAMOND NECKLACE, THE AFFAIR OF THE, a mysterious incident at the court of Louis XVI of France, which involved the queen, Marie Antoinette. The Parisian jewellers Boehmer and Bassenge had spent some years collecting stones for a necklace which they hoped to sell to Mme Du Barry, the favourite of Louis XV, and after his death to Marie Antoinette. They were considerably embarrassed by their failure to do so.

Since his recall in disgrace from Vienna in 1774, Louis, cardinal de Rohan, had been anxious to be reconciled to the queen. In March 1784 he took as mistress a certain Jeanne de St. Reny de Valois, who had married a *sous intendant* comte de Lamotte. She persuaded him that she had been received by the queen and enjoyed her favour, and carried on for him a pretended correspondence with the queen, the adventures duly producing replies to Rohan's notes in the queen's name. The tone of the letters became very warm, and the cardinal, convinced that Marie Antoinette was in love with him, became ardently enamoured of her. A secret meeting took place in Aug. 1784, in a grove in the garden at Versailles, between Rohan and a lady whom the cardinal believed to be the queen herself. Rohan offered her a rose, and she promised him that she would forget the past. The jewellers also believed in the relations of the countess with the queen, and they resolved to use her to sell their necklace. She agreed, and shortly after Rohan purchased it for 1,600,000 livres, payable in instalments. He said that he was authorized by the queen, and showed the jewellers the conditions of the bargain approved in the handwriting of Marie Antoinette. The necklace was given up. Rohan took it to the countess's house, where a man, in whom Rohan believed he recognized a valet of the queen, came to fetch it. Boehmer and Bassenge, before the sale, in order to be doubly sure, had sent word to the queen of the negotiations in her name. Marie Antoinette allowed the bargain to be concluded, and after she had received a letter of thanks from Boehmer, she burned it.

When the time came to pay, the comtesse de Lamotte presented the cardinal's notes, but these were insufficient, and Boehmer complained to the queen, who told him that she had received no necklace and never ordered it. Then followed a *coup de théâtre*. On Aug. 15, 1785, Assumption Day, when the whole court was awaiting the king and queen in order to go to the chapel, the cardinal de Rohan, who was preparing to officiate, was arrested and taken to the Bastille. The police also arrested Mme de Lamotte, and some minor accomplices. A sensational trial before the *parlement* of Paris resulted (May 31, 1786) in the acquittal of the cardinal. The comtesse de Lamotte was condemned to be whipped, branded and shut up in the Salpêtrière. Her husband, who is believed to have escaped with the necklace to London, was condemned, in his absence, to the galleys for life. Various circumstances fortified the popular belief that Marie Antoinette, in her hatred of the cardinal, had deliberately trapped Rohan—her disavowal of the necklace, the fact that he was deprived of his charges and exiled to the abbey of La Chaise Dieu, and finally the escape of the comtesse de Lamotte from the Salpêtrière, with the connivance, as people believed, of the court. Mme de Lamotte, having taken refuge abroad, published *Mémoires*, in which she accused the queen.

DIAN, a patrilineal people closely related to the Lobi and the Gan but more advanced, living near Diebouguo, Gauru district, Upper Volta, Africa.

See Labouret, "La Terre, la chasse et la guerre parmi les populations du Lobi," *Annales et Mémoires, Comité Études Hist. et Scient.* (Dakar, 1916-21).

DIANA, in Roman mythology, an Italian goddess in later times identified with the Greek Artemis (*q.v.*). That she was originally an independent Italian deity is shown by the presence of her cult at Nemi, which shows no foreign influence. This was in a grove beside the lake of (Nemus) Nemi, near Aricia (whence

her title of Nemorensis). Here she was worshipped side by side with an obscure male deity, Virbus (*q.v.*). Her priest, called *rex Nemorensis*, who was a runaway slave, was obliged to qualify for office by slaying his predecessor in single combat (Strabo v. 239; Suetonius, *Caligula*, 15). This led to the identification of Diana with the Tauric Artemis, whose image was said to have been removed by Orestes to the grove of Aricia (see ARGENT).

After the destruction of Alba Longa, this grove was for a long time the united sanctuary of the Latin League, until Rome became supreme. The festival of the goddess was on the ides (13th) of August, the full moon of the hot season. She was worshipped with torches, and was sought by women seeking a happy deliverance in childbirth, and many votive offerings have been found on the site. The worship of Diana was brought to Rome, and her temple on the Aventine was founded, according to tradition, by Servius Tullius, originally as a sanctuary of the Latin League (Dion. Halic. iv. 26.3). On the day of its dedication (Aug. 13) the slaves kept holiday (Plutarch, *Quaest. Rom.*, 100), which was explained as a reference to the founder's servile origin. Another celebrated sanctuary of Diana was that on the slopes of Mount Tifata, near Capri, where she was worshipped under the name of Tifuna.

BIBLIOGRAPHY—See J. G. Frazer, *Golden Bough*, Lang, *Myth and Religion*, p. 205 et seq.; Rose, *Rom. Quest.*, p. 89; Wissowa, *Religion u. Kultus*, p. 247 (2nd ed.).

DIANA MONKEY, a West African gnomon (*q.v.*) taking its name *Ceropitheca diana*, from the white crescent band on the forehead. The general colour is iron gray, a broad chestnut band runs down the lower back and the thigh is crossed with a white band. A beard, white except for the front hairs which are black, decorates the chin. *C. d. roloway*, of the Gold Coast has a longer, pure white beard, *C. d. dryas* of the Congo is similar, but more greenish. (J. E. Hc.)

DIANE DE FRANCE (1538-1619), duchess of Montmorency and Angoulême, was the natural daughter of Henry II of France and a young Piedmontese, Fulipa Duce. She was a beautiful and accomplished girl. She married in 1553 Horace Farnese, son of the duke of Parma, who was killed at the siege of Hesdin shortly after the marriage. In 1559 she married François de Montmorency, one of the leaders of the *politiques*. After her husband's death she exercised a wise and moderating influence at the courts of Henry III and Henry IV successfully.

See Brantôme, ed. by Lalanne in *Coll. de la société d'histoire de France*, Vol. viii (1875); J. de Thou, *Historia sui temporis* (1733); M. de Morgues, *Oraison funèbre de Diane de France* (Paris, 1619).

DIANE DE POITIERS (1499-1566), duchess of Valentinois, mistress of Henry II of France, was the daughter of Jean de Poitiers, seigneur de St. Valier, who came of an old family of Dauphiné. In 1515 she married Louis de Brézé, grand sénéchal of Normandy, by whom she had two daughters. After her husband's death in 1533, she became the mistress of Prince Henry, who became dauphin in 1530. She inspired in the young prince who was twenty years her junior, a passion which lasted until his death. The accession of Henry II in 1547 was also the accession of Diane. She was virtuous queen, while Henry's lawful wife, Catherine de Medici, lived in comparative obscurity. Diane devoted her energies chiefly to augmenting her income, and providing for her family and friends. Henry gave her the duchy of Valentinois. Catherine drove her from the court after Henry's death, and forced her to restore the crown jewels and to accept Chaumont in exchange for Châteaufort. Diane retired to her château at Anet, where she died in 1566.

The story that she had been the mistress of Francis I, in order to obtain the pardon of her father, who had been condemned to death as an accomplice of the constable de Bourbon, has no serious foundation. Diane was a patroness of the arts. She entrusted to Philibert de l'Orme the building of her château at Anet, and it was for her that Jean Goujon executed his masterpiece, the statue of Diane, now in the Louvre.

See G. Guiffrey, *Lettres inédites de Diane de Poitiers* (1866) and *Procès criminel de Jehan de Poitiers* (1867); Capefigue, *Diane de Poitiers* (1860); Hay, *Madame Diane de Poitiers* (1900).

DIANTHUS *see* CARNATION

DIAPASON (Gr *δια πασών*, through all), a term in music originally denoting the interval of an octave. The Greek is an abbreviation of *ἡ δια πασῶν ᾠδῶν συμφωνία*, a consonance through all the tones of the scale. In this sense it is only used now, loosely, for the compass of an instrument or voice, or for a harmonious melody. The name is given to the two foundation stops of an organ, the open and the stopped diapason (*see* ORGAN) and to a standard of musical pitch, as in the French *diapason normal* (*see* PITCH, MUSIC).

DIAPER, the name given to a textile fabric, formerly of a rich and costly nature with embroidered ornament, but now of linen or cotton with a simple woven pattern, and particularly restricted to small napkins.

In architecture, the term "diaper" is given to any small pattern of a conventional nature repeated continuously and uniformly over a surface, the designs may be purely geometrical or based on floral forms, and in early examples were regulated by the process of their textile origin. Subsequently similar patterns were employed in the middle ages for the surface decoration of stone, as in Westminster Abbey and Bayeux cathedral in the spandrels of the arcades of the choir and nave, also in mural painting, stained glass, incised brasses, encaustic tiles, etc. Probably in most cases the pattern was copied, so far as the general design is concerned, from the tissues and stuffs of Byzantine manufacture, which came over to Europe and were highly prized as ecclesiastical vestments.

In its textile use, the term diaper was originally applied to silk patterns of a geometrical pattern, it is now almost exclusively used for diamond patterns made from linen or cotton yarns. An illustration of two patterns of this nature is shown in the figure. The floats of the warp and the weft are mostly in three, indeed the patterns are made from a base weave which is composed entirely of floats of this number. It will be seen that both designs are formed of what may be termed concentric figures—alternately black and white. Pattern B differs from pattern A only in that more of these concentric figures are used for the complete figure. If pattern B, which shows only one unit, were extended, the effect would be similar to A, except for the size of the unit. In A there are four complete units, and hence the pattern appears more striking. Again, the repeating of B would cause the four corner pieces to join and to form a diamond similar to the one in the centre. The two diamonds in B would then alternate diagonally to left and right. Special names are given to certain kinds of diapers, e.g., "bird's eye," "pheasant's eye," these indicate, to a certain extent, the size of the complete diamond in the cloth—the smaller kind taking the name "bird's eye." The size of the pattern on paper has little connection with the size of the pattern in the cloth, for it is clearly the number of threads and picks per inch which determine the size of the pattern in the cloth from any given design. Although A is larger than what is usually termed the "bird's eye" pattern, it is evident that it may be made to appear as such, provided that the cloth is fine enough. These designs, although adapted mostly for cloths such as nursery-drapers, for pinafores, etc., are sometimes used in the production of towels and table cloths. In the figure the first pick in A is identical with the first pick in B, and the part C shows how each interweaves with the 24 threads.

DIAPHONIA, in Greek musical terminology, dissonance, as opposed to consonance. Later, that is, in the early middle ages, the term signified one of the earliest kinds of descant (*see* IT), it is known as organum, in which the parts moved by unvaried parallel motion in fourths and fifths.

DIAPHORETICS, the name given to those remedies which promote perspiration. Among the best known are vapour or hot water baths, or that part of the process of the Turkish bath

which consists in exposing the body to a dry and hot atmosphere. Such measures, particularly if followed by the drinking of hot liquids and the wrapping of the body in warm clothing, seldom fail to excite copious perspiration. Numerous medicinal substances have the same effect.

DIAPHRAGM (di'f-rām) (or mdrif) In human anatomy a large fibro muscular partition between cavities of the thorax and abdomen, it is convex toward the thorax, concave toward the abdomen, and consists of a central tendon and a muscular margin. The central tendon (*see* fig.) is triangular in shape. The fleshy fibres rise, in front, from the back of the xiphoid cartilage, laterally by six serrations, from the inner surfaces of the lower six ribs, posteriorly from the five arcuate ligaments, two external, two in internal and one median. There are three large openings in the diaphragm, the aortic is behind the middle arcuate ligament and transmits the aorta, the vena azygos major, and the thoracic duct. In the right leaflet is an opening for the inferior vena cava and a branch of the right phrenic nerve, while in front and a little to the left of the aortic opening is one for the oesophagus and the two pneumogastric nerves.

Through the crura pass the splanchnic nerves. The sympathetic nerves usually enter the abdomen behind the internal arcuate ligaments. The phrenic nerves, which are the main supply of the diaphragm, divide before reaching the muscle and pierce it in a number of places to enter its abdominal surface, but some of the lower intercostal nerves assist in the supply.

For the action of the diaphragm *see* RESPIRATORY SYSTEM, ANATOMY OF.

Embryology.—The diaphragm is at first developed in the neck region of the embryo, and this accounts for the phrenic nerves, which supply it, rising from the fourth and fifth cervical. With growth of the body and development of the lungs the diaphragm shifts its position downward. (*See* A. Keith, "On the Development of the Diaphragm," *Journal of Anat. and Phys.* vol. 39.)

A Paterson has recorded cases in which the left half of the diaphragm is wanting (*Proceedings of the Anatomical Society of Great Britain*, June 1900, *Journal of Anat. and Phys.* vol. 34), and occasionally deficiencies are found elsewhere, especially in the sternal portion.

Comparative Anatomy.—A complete diaphragm is characteristic of the Mammalia, it usually has the human structure and relations except that below the Anthropoids it is separated from the pericardium by the azygous lobe of the lung. In some mammals, e.g., Echidna and Phocoena, it is entirely muscular. In the Cetacea it is remarkable for its obliquity, this allows a larger lung space in the dorsal than in the ventral part of the thorax and may be concerned with the ejection of the animal. Below the mammals incomplete partitions are found in chelonians, crocodiles and birds, and in amphibians (*Xenopus* and *Pipa*).

DIAPHRAGM. *see* GRAMOPHONE, MICROPHONE, TELEPHONE.

DIARBEKR or DIYARBEIR, chief town of a vilayet of Turkey, situated on a basaltic plateau on the right bank of the Tigris, which there flows in a deep open valley. The town is still surrounded by the masonry walls of black basalt which give it the name of Kara or Black Armid, they are well built and imposing on the west facing the open country, but almost in ruins where they overlook the river. A mass of gardens and orchards covers the slope down to the river on the southwest. Pop. (1900) 42,555. The streets are narrow, badly paved and dirty, the houses and shops are low, mostly of stone and some of stone and mud. The bazaar is a good one, and gold and silver filigree work is made. From Diar, land, and Bekr (*see* Abu Bekr, the caliph)

DIAPER A AND B SHOW TWO VARIETIES OF DIAMOND PATTERN. DIAPERS A AND C SHOWS THE WARP AND WEFT.

THE DIAPHRAGM. THE CHIEF MUSCLES OF RESPIRATION. Abdominal surface showing origin of central tendon (C) from xiphoid cartilage (D) and openings for aorta (K) inferior vena cava (M) pneumogastric nerves (L) and oesophagus.

peculiar in character and design. Trut is good and abundant as the rich volcanic soil is well watered from the town springs. The size of the melons is specially famous. To the south, the walls are some 40 ft. high, faced with large cut stone blocks of very solid construction, with towers and square bastions rising to 50 ft. There are four gates, on the north the Kharput gate, on the west the Rum, on the south the Mardin and on the east the Vem Kapu or new gate. A citadel enclosure stands at the northeast corner and is now partly in ruins, but the interior space is occupied by the government konak. The summer climate in the confined space within the town is excessively hot and unhealthy. Winters are frequently severe but do not last long. The town is supplied with water both by springs inside the town and by aqueducts from fountains at Ali Pinar and Hürmervit. The principal exports are wool, mohair and copper ore, and imports are cotton and woollen goods, indigo, coffee, sugar, petroleum, etc. Cereals, cotton, tobacco, rice and silk are produced, and a school has been opened to give villagers instruction in silkworm culture. An exceptionally rich copper mine exists at Arghana Maden, galena mineral oil and silicious sand are also found. Scorpions noted for their virulence abound.

The Great Mosque, Ulu Jama, formerly a Christian church, occupies the site of a Sassanian palace and was built with materials from an older palace, probably that of Tigranes II. The churches of greatest interest are those of SS. Cosmas and Damián (Jacobite) and the church of St. James (Greek). In the 19th century Diarbekr was one of the largest and most flourishing cities of Asia. It is at the head of the navigation of the Tigris, which is traversed downstream by keleks or rafts supported by inflated skins. There is a good road to Aleppo and Alexandretta on the Mediterranean, and to Samson on the Black sea by Kharput, Malatia and Sivas. There are also routes to Mosul and Bithlis. Railroad service to Dyrbektir from Ankara was inaugurated on Nov. 22, 1935.

Durbektir became a Roman colony in A.D. 230 under the name of Amida. It was enlarged and strengthened by Constantius II, in whose reign it was taken after a long siege by Shapur (Sapor) II, king of Persia. The historian Ammianus Marcellinus, who took part in the defense, gives a detailed account of it. In the later wars between the Persians and Romans it more than once changed hands. Though ceded by Jovian to the Persians it again became annexed to the Roman empire, and in the reign of Anastasius (A.D. 492) was once more taken by the Persians. It was taken c. 638 by the Arabs, and afterward passed into the hands of the Seljuks and Persians, from whom it was finally captured by Selim I in 1515, and from that date it has remained under Ottoman rule. About 2 mi. below the town is a masonry bridge over the Tigris, the older portion being probably Roman, and the western part, which bears a Kufic inscription, being Arab.

(C W W, F R M)

DIARRHOEA, a looseness of the bowels with frequent soft or watery stools which may contain mucus and blood, usually accompanied by griping pain or colic, may be due to many causes, which differ somewhat in adults and in children.

In adults primary diarrhoea may be due to diet, constipation, changes of climate or weather, to irritants taken with food (mushrooms (death cap or deadly agaric), mercury, arsenic or opium poisoning, to alterations of intestinal secretion or absorption

or other worm infections, to general infections (endocarditis, septicaemia and pulmonary tuberculosis, to diseases of the intestines carcinoma, tuberculosis, syphilis, actinomycosis, diverticulitis,

Crohn's disease (regional ileitis), peritonitis, appendicitis and haemorrhoids, to blood diseases. Hæmochs and other forms of purpura, to chronic circulatory disturbances (portal congestion, cirrhosis of the liver, chronic heart and lung diseases, to various causes, hyperthyroidism (hyperthyroidism), chronic alcoholism, uraemia and lardaceous diseases, to avitaminosis pellagra and other vitamin B₂ deficiencies. There are also a few special types of diarrhoea: various forms of colitis and polyposis, stercoral ulceration of the bowel and foreign bodies in the rectum.

Diarrhoea in children may be classified as follows: diarrhoea and vomiting (summer diarrhoea), diarrhoea from chills and errors in diet, acute gastroenteritis, the bacillary dysenteries (amoebic dysentery (rare), colic disease (fatty diarrhoea), missusaceticum and polyposis (See DYSENTERY). (P H M-B)

DIARY, the book in which are preserved the daily memoranda regarding events and actions which come under the writer's personal observation or are related to him by others. The person who keeps this record is called a diarist.

It is not until the close of the Renaissance (but see COMMENTARI) that we find diaries beginning to have literary value. In the 17th century they began to be largely written in England although in most cases without any idea of even eventual publication. Sir William Dugdale (1605-86) had certainly no expectation that his slight diary would ever see the light. Bulstrode Whitelocke (1605-75), whose *Memorials of the English Affairs* covers the ground from 1625-60, was a genuine diarist. So was the elder George Fox (1624-91), who kept not merely "a great journal," but "the little journal books," and whose work was published in 1694.

The famous diary of John Evelyn (1620-1706) professes to be the record of 70 years and, although large tracts of it are covered in a very perfunctory manner, while in others many of the entries have the air of having been written in long after the event, this is a very interesting and amusing work; it was not published until 1818. It would hold a still higher position in the history of literature than it does if it were not overshadowed by what is unquestionably the most illustrious of the diaries of the world, that of Samuel Pepys (1633-1703) (q.v.). This was begun on Jan. 1, 1660, and was carried on until May 29, 1669. The extraordinary value of Pepys's diary consists in its fidelity to the portraiture of its author's character. In the age which succeeded that of Pepys, a diary of extraordinary emotional interest was kept by Jonathan Swift from 1710 to 1713, and was sent to Ireland in the form of a *Journal to Stella*, it is a surprising amalgam of ambition, affection, wit and freakishness. John Byrom (1692-1763), the Manchester poet, kept a journal, which was published in 1851.

The diary of the celebrated dissenting divine, Philip Doddridge (1702-51), was printed in 1829. Of far greater interest are the admirably composed and vigorously written journals of John Wesley (1703-91). But the most celebrated work of this kind produced in the latter half of the 18th century was the diary of Fanny Burney (Madame d'Arblay), published in 1842-46. It will be perceived that, without exception, these works were posthumously published. James Boswell's *Journal of a Tour to the Hebrides* (1785), a genuine diary though somewhat expanded, was published during the author's lifetime.

Many of the diaries described above were first published in the opening years of the 19th century, and the interest which they awakened led to their imitation. Diaries ceased to be rare, but as a rule those which appeared did not present much literary interest. Sir Walter Scott's *Journal* (published 1800) and the diaristic portions of R. B. Haydon's *Autobiography and Journal* are eminent exceptions. Exception must also be made in favour of the journals of two minor politicians, Charles Greville (1794-1865) and Thomas Creevey (1768-1838), whose indiscretions added much to the gaiety of nations, the papers of the former appeared in 1874-87, those of the latter in 1903. The diary of Henry Crabb Robinson (1775-1867), printed in 1869, contains excellent biographical material. Tom Moore's journal, published in 1856 by Lord John Russell, disappointed its readers. Charles Darwin's historic *Voyage Round the World* is written in diary form. R. W. Emerson's *Journals* are the notebook of an author rather than a

book of intimate confessions. In the 20th century many men and women published their diaries during their lifetimes. Col. Charles Repington's diary of World War I was a monument of indiscretion. "W. N. P. Birrell" was still alive when his tragic *Diary of a Disappointed Man* was published. Of recent diaries none has possessed more literary grace than the *Journal of Katherine Mansfield*.

It was natural that the form of the diary should appeal to a people so sensitive to social peculiarities as the French. A medieval document of immense value is the diary kept by an anonymous curé during the reigns of Charles VI and Charles VII. This *Journal d'un bourgeois de Paris* was kept from 1409 to 1431, and was continued by another hand until 1449. The marquis de Dangeau (1638-1700) kept a diary from 1684 till the year of his death; this is an inexhaustible storehouse of facts about the reign of Louis XIV. Saint Simon's own brilliant memoirs, written from 1691 to 1723, may be considered as a sort of diary. The lawyer, Edmond Barbier (1689-1771), wrote a journal of anecdotes from 1718-62.

The song writer, Charles Collé (1709-83), kept a *journal historique* from 1758 to 1782; it is full of vivacity, but very scandalous. Petit de Bachaumont (1690-1771) had access to remarkable sources of information, and his *Mémoires secrets* contains a valuable mass of documents. The posthumous publication of the diaries of the Russian artist, Marie Bashkirtseff (1860-84), produced a great sensation in 1887. The brothers Jules and Edmond de Goncourt kept a very minute diary of artistic and literary Paris, after the death of Jules, in 1870; this was continued by Edmond, who published the first three volumes in 1888.

DIAPORE, an aluminum oxide, Al_2O_3 , isomorphous with goethite. It occurs as platy orthorhombic crystals and as lamellar or scaly masses, the flattened surfaces being the direction of a perfect cleavage and having a markedly pearly lustre. It may be colourless, grayish, greenish, brownish, yellowish or pink and sometimes violet with marked pleochroism. It is readily distinguished from other common platy minerals, such as mica, talc, gypsum and brucite, by its greater hardness, 6.5 to 7. The specific gravity is 3.4.

When heated in the blowpipe it decrepitates violently, forming white scales, hence the name from the Greek *diapora*, a scatter ring. It is associated with corundum and at times is a major constituent of bauxite and aluminous clays. (L. S. RL.)

DIASTYLE, an intercolumniation (*q.v.*) of three or four diameters.

DIA THERMY, a term first applied by C. F. Nagelschmidt in 1908 to the use of alternating currents of high frequency for heating locally the tissues of the body. The frequencies employed are 300,000 cycles or higher, which are too rapid to affect the nerve endings. Hence currents of an ampere or more can be used the patient feeling only a sensation of warmth. The currents are generated in a coil of appreciable inductance and very low resistance by the oscillatory discharge of a condenser. The condenser is charged to a high voltage by a step-up transformer on an A.C. supply, and the discharge is produced by the passage of a spark through a multiple tungsten-faced spark gap. The oscillations are of the necessary high frequency and are maintained continuously by the spark discharge. The currents act led to the patient by pads of flexible metal sheets. (See ELECTROTHERAPY AND ELECTRODIAGNOSIS.) (F. L. A.)

DIA TOMACRAE, see BACILLARIOPHYCEAE or DIATOMS.

DIA TOMACROUS EARTH (DIATOMITE) is a hydrous form of silica or opal composed of the siliceous shells of diatoms, which are uncelled aquatic plants of microscopic size. It is light coloured and occurs in sedimentary beds that somewhat resemble chalk, but it is much lighter and will not effervesce in acid. Under a high powered microscope the form of the diatoms can be distinguished. These are so small and abundant that several million are contained in one cubic inch of diatomite. Many thousands of different varieties are known and diatoms are living today in some bodies of fresh and salt water where the shell sink to the bottom when the organisms die. The largest deposit worked in the United States is in northern Santa Barbara county

near Lompoc, Calif. Miocene beds more than 2000 ft thick are known to extend over several square miles and vary from soft earth to hard compact rock that can be stewed into blocks. The principal production in the United States has come from these deposits in California and those of Oregon, but some also has been produced in Idaho, Nevada, New York and Washington. The main uses are for pressure filtration of oil, sugar, syrups and cereal beverages, for heat and sound insulation, for fillers, and for fine abrasives such as silver polish. In Europe it has been used as the inert ingredient of nitroglycerin. (V. T. A.)

DIA TONIC, a musical term signifying literally "through the tones," otherwise music in which the notes employed are confined to those of the key, major or minor as the case may be, in which it is written. Hence diatonic music gives a general impression of strength, simplicity and solidity as distinguished from the more restless and poignant character of chromatic (*q.v.*) music in which notes from foreign keys are introduced by accidentals (*q.v.*). The diatonic was one of the three Greek genera of scale. (See Music: Non-Harmonic and Greek Music.)

DIA TRYMA, a group of extinct birds known from the Eocene fossil deposits of New Jersey, Wyoming and New Mexico. These were huge flightless species as large as the larger of the extinct moas of New Zealand or the fossil *Phororhacos* of South America, developed for an active, aggressive terrestrial life. *Diatryma steini*, described by W. D. Matthew and Walter Granger from a nearly complete skeleton, stood almost seven feet high.

The neck was short and strong and the head huge, the skull being 17 in. long with a compressed beak which, as preserved with out the horny rhamphotheca, measures 9 in. long and 6½ in. high. The postorbital and squamosal are joined distally to form a temporal fenestra. The mandible is massive, though having a slender tip, with strong muscular attachments.

The coracoid and scapula are fused, and the humerus much reduced, the wing being completely nonfunctional for flight. The pelvis and leg are large and strong, the femur being 15 in. long and the tibia nearly 2 ft. The metatarsus is incompletely preserved, but is a heavy bone with two perforations of the shaft at the upper end. The three anterior toes are strong while the hallux is small and elevated.

Three other species, *Diatryma ajax*, *D. giganteum* and *Onomophus storchii* have been described and another, *Baronius regens* from the Eocene of New Jersey, is placed with these somewhat uncertainly. *Diatryma sarasinum* was named from Montehlon near Epemay, Fr. These form the family Diatrymidae, which is placed in the order Diatrymiformes near the Cranes with which, however, it does not show close affinity.

The fossil family of the Gastornithidae, represented by six species from the Eocene of western Europe, is placed tentatively in this order.

BIBLIOGRAPHY—W. D. Matthew, and Walter Granger, "The Skeleton of *Diatryma*, a Gigantic Bird from the Lower Eocene of Wyoming," *Bull. Amer. Mus. Nat. Hist.*, vol. xxvii, pp. 307-346 (1917). Källman, Lambrecht, *Handbuch der Palaeornithologie*, pp. 566-579 (1933). (A. W. T.)

DIAULOS, originally, in Greece, a race of twice the usual length, or two stadia, also, in architecture, the colonnade surrounding the great court of the Greek palaestra, so called because its total circuit was about two stadia, or about 1,200 ft.

DIAVOLO, FRA (1771-1806), the popular name given to a famous Italian brigand. His real name was Michele Pezza, and he was born of low parentage at Itri, he had committed many murders and robberies in the Terra di Lavoro, but escaped capture, whence his name, popular superstition having invested him with the characters of a monk and a demon, and it seems that at one time he actually was a monk.

Fra Diavolo was made leader of one of the bands raised by the Bourbon king Frederick IV against the French occupation, and succeeded in interrupting the enemy's communications between Rome and Naples. But although he wore a military uniform and held military rank, and was even created duke of Cassano, his atrocities were worthy of a bandit chief. On one occasion he threw some of his prisoners, men, women and children, over a precipice, and on another he had a party of 70 shot. He was for a short time

imprisoned in the castle of St. Angelo, but was soon liberated. Joseph Bonaparte put a price on Fra Davello's head. For some time he evaded his pursuers but at length, hungry and ill, tired in disguise to the village of Baronissi, where he was arrested, tried by an extraordinary tribunal, condemned to death and shot. His name has gained a world wide celebrity as the title of a famous opera by D. Auber.

See A. Luzio, *Profilo e bozzetti storici* (Milan, 1906).

DÍAZ, ARMANDO (1861-1928), Italian marshal, was born in Naples on Dec. 6, 1861. He served in the Italo Turkish War, and in 1914 was promoted to major general. On Italy's entry into World War I he was director of military operations, and in 1916 became lieutenant general in command of the 49th division. In 1917 he was put in command of the 13th corps and saw much hard fighting on the Carso.

In Nov. 1917 after Caporetto, Diaz succeeded Luigi Cadorna as chief of the general staff. Under him the battle front was successfully reconstituted and the Austrian armies were destroyed at Vittorio Veneto (Oct.-Nov. 1918). After the signature of the Armistice he became inspector general of the army. He received many honours, Italian and foreign, and in 1921 was created duca della Vittoria.

On the advent of the fascist government he was appointed minister of war, and held that appointment until ill health obliged him to resign in April 1924. On Nov. 4, 1924, the newly created rank of marshal was conferred on him. He died on Feb. 29, 1928, at Milan.

DÍAZ, JOSÉ DE LA CRUZ PORFIRIO (1830-1915), Mexican soldier and statesman, born in the city of Oaxaca, state of Oaxaca, Sept. 15, 1830. His family was poor, and his mother was part Indian. He was educated for the church, then the only career open to a youth without wealth. At the age of 15 he entered the Seminario Pontifical in Oaxaca, but in 1849, falling under the influence of Benito Juárez, rector of the university, he relinquished his clerical ambitions to undertake the study of law with Juárez in the Institute of Arts and Sciences, where he passed his examinations in civil and canon law in 1853. But he was pre-eminently a man of action. During the war with the United States (1847-48) he left home to serve in the army. In the plebiscite of 1855 he repudiated the dictatorship of Antonio de Santa Anna. When the anticlerical measures of the constitution of 1857 resulted in the War of Reform (1858-61), Diaz supported Juárez then president of the country, and aided materially in the overthrow of the clerical revolution and the final establishment of the Reform laws.

He was one of the first to oppose the French invasion of 1862 and, after the establishment of Maximilian in Mexico in 1864, he was the most prominent figure in the struggle against the empire. He defeated a French attack upon Puebla in 1862 and in 1865, when the republican forces seemed at their nadir, he formed the "army of the east," recaptured Puebla in the spring of 1867 and on June 21, 1867, two days after the execution of Maximilian at Querétaro, re-entered the capital. Placing the city under martial law he maintained order until he was able to hand over his command to Juárez. Then he resigned his position in the army and retired to Oaxaca. He took no part in the government until 1871. Dissatisfied with Juárez' policy, he appeared as a candidate for the presidency against Juárez and Sebastián Lerdo de Tejada, and when congress proclaimed the re-election of Juárez, led an unsuccessful revolt in protest. In 1872 Lerdo succeeded as president in an administration which brought discord and disorder, and when he attempted to be re-elected in 1876, Diaz took the leadership of a revolution, proclaimed the principle of non-re-election and defeated the government forces in the battle of Teocac, on Nov. 16, 1876. He was elected president in May 1877, and at once forged ahead with financial and political reform, the centralization of the government, the re-establishment of public security the scrupulous settlement of all national debts and the building of railroads and telegraphs. His rule was stern, his methods sometimes brutal, but he achieved amazing results.

In 1880 he was succeeded by Manuel Gonzalez the former minister of war, in whose cabinet he sat for some time as minister

of fomento, but in 1884 was unanimously re-elected to the presidency. Continuing his program of political reorganization and economic reform, he opened the nation's natural resources to the world, succeeded in attracting great quantities of foreign capital and won for Mexico, for the first time in its history, a position of respect among the nations. Political crises which arose with Guatemala, Austria and the United States he handled to the advantage of Mexico. In 1887 and 1892 the constitution was amended to permit his re-election and from 1884 until 1911 he was continuously in office. But material prosperity was achieved at the cost of repression and increasing discontent. The land problem became acute, education was inadequate, and agitators fomented widespread dissatisfaction at the alleged control of the country by foreign capitalists. An incipient revolt headed by Gen. Bernardo Reyes in 1903 was quickly crushed, but in 1910 the standard of agrarian revolt was raised. The movement spread swiftly over the country, the government was unable to control the army and on May 4, 1911, Diaz resigned his post and left for Europe. He died in Paris on July 2, 1915, having seen destroyed most of the stability which he had brought to his country.

DÍAZ, NARCISSE VIRGILE (1809-1876), French painter of the Barbizon school, was born in Bordeaux of Spanish parents on Aug. 25, 1809. At first a figure painter who indulged in strong colour, in his later life Diaz became a painter of the forest and a tone artist of the first order.

He had an unhappy childhood. He lost a leg through a badly dressed insect bite, and worked for some time as a porcelain painter at Sévres. About 1831 at Diaz encountered Théodore Rousseau for whom he entertained a great veneration although Rousseau was four years his junior. Ten years later Diaz found Rousseau painting his wonderful forest pictures, and determined to paint in the same way if possible. Rousseau was touched with the passionate words of admiration, and finally taught Diaz all he knew. Diaz exhibited many pictures at the Paris Salon, and was decorated in 1851.

After 1871 he became fashionable and he worked constantly and successfully. In 1876 he caught cold at his son's grave, and on Nov. 18 of that year he died at Mentone. Diaz' finest pictures are his forest scenes and storms. There are several fairly good examples of his work in the Louvre. Perhaps the most notable of Diaz' works are "La Fee aux Perles" (1857), in the Louvre, "Sun set in the Forest" (1868), "The Storm" and "The Forest of Fontainebleau" (1870) at Leeds. Diaz had no well-known pupils, but Léon Richet followed markedly his methods of tree painting, and J. F. Millet at one period painted small figures in avowed imitation of Diaz' then popular subjects.

See A. Husin, *Les Artistes célèbres* Diaz, J. Claretie, *Peintres et sculpteurs contemporains* Diaz (1884). D. C. Coltham, *The Barbizon School of Painters* (1890). J. W. Mallet, *Diaz* (1890).

DÍAZ DEL CASTILLO, BERNAL (1492-c. 1581), Spanish soldier and author, was born at Medina del Campo. In 1514 he visited Cuba and five years later accompanied Cortez to Mexico where he died.

He is known chiefly by his *True Account of the Discovery of*

DIAZO COMPOUNDS. Diazo compound is a term used

The most important method of preparation is by the action of nitrous acid on a primary aromatic amine in presence of a mineral acid $\text{Ar-NH}_2 + \text{ONOH} + \text{HCl} \rightarrow \text{Ar-N}_2\text{Cl} + \text{H}_2\text{O}$. If the solid diazonium salt is required, the reaction can be carried out by passing nitrous fumes into a paste of the amine hydrochloride and water, addition of alcohol and ether to the resulting solution precipitates the diazonium chloride. The solid salts are explosive and are seldom prepared. In the vast majority of cases an aqueous solution suffices and is obtained by adding sodium nitrite to a solution of the amine in excess (two to three equivalents) of the mineral acid. The temperature must usually be kept below 10°C during and after the reaction because of the decomposition of the diazonium salt at room temperatures and above. Other methods,

and are evolved as gaseous nitrogen and those in which they are retained in the molecule of the product. In the first class the diazo group is replaced by some other group. Examples are:

1. Replacement by hydroxyl, leading to a phenol, usually takes place easily by warming the aqueous solution of the diazonium salt

Side reactions may interfere, especially the coupling of the phenol with an undecomposed diazo compound, and this can be avoided by working in strongly acid solution or by passing steam into the solution to remove the phenol as it formed

2. Replacement by hydrogen is brought about by reducing agents such as formic acid, hypophosphorous acid and sodium stannite. Addition of alcohol often gives the same result but sometimes the ethoxy compound, ArOC_2H_5 , is formed together with, or instead of, ArH . This reaction is of value where an amino group has been introduced to act as a powerful directing group for some desired substitution. The amino group can later be eliminated by diazotization and replacement by hydrogen

3. Replacement by halogen takes place readily with iodine since diazonium iodides decompose spontaneously into nitrogen and the iodo compound. With chlorine the usual methods are to treat the diazonium chloride with cuprous chloride (Sandmeyer's reaction) or with finely divided copper (Gattermann's reaction). Similar methods are used for bromine. Fluorine is best introduced by precipitating the sparingly soluble borofluoride, $[\text{ArN}_2]\text{BF}_4$, by adding borofluoric acid to the solution. The dry borofluoride decomposes smoothly on heating into boron trifluoride, nitrogen and the fluoro compound

4. Replacement by cyanogen can be achieved by Sandmeyer's method, by use of a solution of cuprous cyanide in potassium cyanide. Since the product is a nitrile, it can be hydrolyzed to a carboxylic acid and the reaction is valuable for effecting the change $\text{ArNH}_2 \rightarrow \text{ArCOOH}$

Groups containing sulphur can be linked to the aromatic ring in a variety of ways and the processes are of technical importance since they give intermediates for the preparation of dyestuffs containing sulphur. An example is to treat the diazo compound with potassium ethyl dithiocarbonate (xanthogenate). The product, $\text{ArSCSC}_2\text{H}_5$, can be hydrolyzed to the thiophenol, ArSH , or heated alone to give the thioether, ArSC_2H_5

Linkage between carbon atoms sometimes occurs in the decomposition of diazonium compounds, especially when a new aromatic structure is formed. An example is R Pschorr's synthesis of phenanthrene-carboxylic acid by the decomposition of diazotized α -amino- α -phenylcinnamic acid

There is good evidence to show that the reactions mentioned so far are those of the positively charged aromatic radical formed by loss of nitrogen from the diazonium cation

Of the second class of reactions, in which nitrogen is not lost, an example is reduction to a hydrazine, ArNHNH_2 , this is carried out with stannous chloride or sulphites and is the general method for preparing the valuable reagents, phenylhydrazine and its substitution products. An important example of this class is the coupling reaction which leads to the formation of azo compounds ($q.v.$) While the older view was that the diazonium ion does not couple, recent work shows that the most probable mechanism with phenols is coupling between the diazonium ion and the phenoxide ion, and with amines, coupling between the diazonium ion and the undissociated amine molecule (*cf.* Richard Wistlar and Paul D. Bartlett, "Kinetics and Mechanism of the Coupling of Diazonium Salts With Aromatic Amines in Buffer Solutions," *J. Am. Chem. Soc.*, vol. 63, pp. 413-417 [1941], Louis P. Hammett, *Physical Organic Chemistry* [1940]). Coupling with aromatic amines and phenols is of technical importance since many of the aminoazo and hydroxyazo compounds formed are useful dyes. Thus, diazotized paranitro-

transiline couples in alkaline solution with β -naphthol to give a red dye (para red) much used for cotton

Coupling also takes place with aliphatic amines, phenolic ethers, aliphatic β -ketonic esters and β -diketones and with reactive unsaturated hydrocarbons such as isoprene. In some cases the product first formed is not the azo compound, thus primary amines, both aliphatic and aromatic, often give diazoamine compounds ArN=NHR , such a product can, however, usually be transformed into the azo compound. Because of the technical importance of the reaction there is an enormous mass of empirical knowledge on the rates of coupling and conditions and factors which affect the reaction. Nevertheless, the actual mechanism remains to a large extent obscure

Constitution of the Aromatic Diazo Compounds.—The reasons for the structures of the various forms of a diazo compound which have been given above can be summarized as follows: a diazonium salt behaves as the salt of a strong base and resembles a salt of an alkali metal. The carbonate is soluble in water with an alkaline reaction. The salt must contain a cation similar to that of a quaternary ammonium salt and hence one nitrogen atom must be tetravalent. Christian Blomstrand's view that this cation is $[\text{ArN}=\text{N}]^+$ is clearly correct. In the normal diazotate, formed when the salt is treated with alkali in excess, the diazo group is an anion. A change must have occurred in which the hydroxyl group becomes covalently linked in such a position that it has weak acidic properties. F. A. Kekule's formula, $\text{ArN}=\text{NOH}$, satisfies this condition, the acidic properties finding a close parallel in those of the oximes ($q.v.$) which contain the group NOH . Heated with excess alkali, the diazotate is converted into the isodiazotate which, though more stable, resembles the normal diazotate in all its properties. The two anions must be geometrical isomers which can be represented by the formulas,

A parallel case is that of the geometrically isomeric oximes ($q.v.$) The main reason for this view is that a similar isomerism occurs in the diazo sulphonates, $\text{ArN=N}\text{SO}_3\text{K}$, and the diazo cyanides, $\text{ArN=N}\text{CN}$, and all these cases must almost certainly arise from a common cause which can only be geometrical isomerism. In the diazo cyanides careful study of the physical properties shows that any other type of isomerism is excluded. It also shows that the more stable isomer has the trans configuration so that on the presumption that all the more stable forms have the same configuration the isodiazotate is I and the diazotate is II. Finally, treatment of an isodiazotate with a weak acid gives first the isodiazohydrate, $\text{ArN=N}\text{OH}$, itself a weak acid, and this in chloroform solution changes into a yellow isomer which has no acidic properties. The behaviour recalls that of the aliphatic nitro compounds, where a pseudo acid form exists, and suggests that the yellow solid is the primary nitrosamine, ArNHNO . A point where there was still uncertainty at mid-20th century was the constitution of diazonium salts in the solid state. The sulphates and chlorides are colourless solids which behave as true salts, but some salts, notably the iodides, are so unstable that they hardly exist and the bromides are often yellow and less stable than the

chlorides Hantzsch's view that an equilibrium of the type $(\text{Ar N=N})\text{Br} \rightleftharpoons \text{Ar N N Br}$ exists would seem to have little to recommend it.

Diazo compounds of the aromatic type occur not only in the benzene and naphthalene series but also in most heterocyclic aromatic systems, such as pyrazoles, thiazoles and triazoles. With pyridine and quinoline only the β amino compounds can be diazotized. The reason why diazo compounds of this kind are formed in the aromatic but not in the aliphatic series has something to do with conjugation of the unsaturated diazo group with the aromatic system.

ALIPHATIC DIAZO COMPOUNDS

These compounds contain the grouping $>\text{C}=\text{N}_2$ and are sharply differentiated from the aromatic diazo compounds in that they show neither basic nor acidic properties. With the exception of diazomethane, which is used in the laboratory as a methylating agent, they have little practical interest, but the problem of the structure of the group was a subject of dispute for many years and was solved only when quantum mechanics gave a clearer picture of chemical valency.

There are three chief methods for obtaining these compounds: 1. Diazomethane, CH_2N_2 , and diazoethane, CH_3CHN_2 are formed when nitroso N-methyl (or ethyl) urethane is hydrolyzed with methanolic potassium methoxide. There is evidence that in intermediate in the reaction is an unstable salt analogous to the aromatic diazoate.

This method of H. von Pechmann was modified by A. Arndt, methylurea can be prepared from technical methylamine hydrochloride and potassium cyanate and forms an N-nitroso derivative which is hydrolyzed to diazomethane. The method was generalized by J. Kenner who showed that many primary aliphatic amines form addition compounds with methyl oxide of formula $\text{RCH}_2\text{-NH(CH}_3)_2\text{COCH}_2\text{COCH}_3$. These are secondary amines and their nitroso derivatives give diazo compounds on hydrolysis.

2. A limited number can be prepared by Theodor Curtius' method. The vast majority of aliphatic primary amines react with nitrous acid to give the corresponding alcohol, aliphatic diazo compounds are, however, given by a few, such as esters of α aminoacids (but not the acids themselves), α aminonitriles and α amino ketones, such as ω aminoacetophenone, $\text{C}_6\text{H}_5\text{COCH}_2\text{-NH}_2$. Diazo acetic ester is obtained this way.

3. Oxidation of the hydrazones of aldehydes and ketones is often a useful method. Thus, diphenyldiazomethane, $(\text{C}_6\text{H}_5)_2\text{CN}_2$, is obtained by shaking benzophenone hydrazone with yellow mercuric oxide in cold petroleum ether for six hours.

The aliphatic diazo compounds vary in stability over a wide range. Those with hydrocarbon residues attached to the diazo group are coloured and unstable, those with a carbonyl or carboxy group on the next carbon atom such as diazoacetone, diazoethyl acetate and more stable, while those with two such groups, as $\text{C}_6\text{H}_5\text{COCH}_2\text{COCH}_3$, are colourless and comparatively unreactive, so much so that at one time they were allotted a different constitution. Diazomethane is a deep yellow gas boiling at -23°C , higher members are liquids or low melting solids. Nearly all explode on rapid heating but are reasonably stable in solution. In some of their reactions there is a superficial resemblance to the aromatic diazo compounds in that nitrogen is lost from the molecule thus with dilute aqueous acids the elements of water are added on to give a hydroxy compound, $>\text{CN}_2 \rightarrow >\text{CHOH}$. A similar reaction takes place with many classes of compounds containing the $-\text{OH}$, $-\text{NH}_2$ and NH groups and it is for this reason that diazomethane is a valuable methylating agent. When the diazo compounds decompose spontaneously, a variety of products is formed which arise from the reactions of the methylene radical formed by a simple loss of nitrogen from the molecule. Thus, the ethylenic compound $\text{R}^1\text{C}=\text{C}^1\text{R}^2$ is a frequent product. Another characteristic set of reactions is addition to unsaturated compounds. These often take place without loss of nitrogen to give heterocyclic compounds of the pyrazole and pyrazoline series.

Sometimes nitrogen is lost in a subsequent stage and a cyclopropane derivative formed, a striking example is the addition of diazoacetic ester to benzene, one of the few reactions in which the latter shows simple ethylenic behaviour.

The structure of the characteristic group $>\text{CN}_2$ was a matter of controversy for many years. Curtius in 1883 proposed the formula

which was accepted until A. Engel in 1907 pointed out that the relationship to hydrazones both in oxidation and reduction, was evidence for a straight chain formula which he wrote as $>\text{C}=\text{N}=\text{N}$. Electron diffraction by diazomethane vapour (H. Boersch, 1935) shows beyond doubt that the straight chain is correct. Engel's formula is, however, inconsistent with modern views on the valency of nitrogen and the actual structure must be that of a resonance hybrid between $>\text{C}=\text{N}=\text{N}$ and $>\text{C}-\text{N}=\text{N}$. This view is supported by the known distances between the atoms of the group. This is one of the few cases where no one formula based on the older ideas of valency can be satisfactorily given.

(T. W. J. T.)

DIBDIN, CHARLES (1745-1814), British composer and entertainer, was born in Southampton c. March 4. From 1756 to 1759 he was a chorister at Winchester cathedral, in 1760 he was engaged as singer-actor at Covent Garden where his first opera was produced in 1764. Of a restless and irascible disposition, he lived an unsettled life and several of his theatrical ventures were ended by quarrels. During an engagement as actor and composer at Drury Lane theatre (1768-76) he produced two successful works—*The Waterman* (1774) and *The Quaker* (1775). Later (1785) his ballad opera, *Liberty Hall*, containing the song "The Bells of Aberdovey," was also produced there. His fame as a song writer rests mainly on the stirring sea songs he introduced into his one-man "table entertainments" which were popular from 1789 to 1806, the best known is "Tom Bowling."

In 1791 he opened his own theatre, the Sans Souci, and also became his own publisher. In addition to about 100 dramatic pieces and 1,400 songs, he wrote his autobiography, *Professional Life* (1803), a *History of the Stage* (1795) and *The Musical Tour of Mr. Dibdin*, an account of his tour through England in 1787-88 to raise money for a projected, but abortive, visit to India. He also wrote several novels. He died in London on July 25, 1814. His sons, Charles and Thomas John Dibdin, were popular dramatists, and his grandson, Henry Edward Dibdin, was compiler of the *Standard Psalm Tune Book* (1857).

DIBDIN, THOMAS FROGNALL (1776-1847), English bibliographer born at Calcutta, was the son of Thomas Dibdin, the sailor brother of Charles Dibdin. He was educated at St. John's college, Oxford, and was entered at Lincoln's Inn. After an unsuccessful attempt to obtain practice as a provincial counsel at Worcester, he was ordained at the close of 1804, being appointed to a curacy at Kensington. In 1803 he received the living at Exning in Sussex. Soon afterward he was appointed by Lord Liverpool to the rectory of St. Mary's, Bryanston square, which he held until his death.

The first of his numerous bibliographical works was his *Introduction to the Knowledge of Editions of the Classics* (1802), which brought him under the notice of the third Earl Spencer, who threw open to him the rich library at Althorp, he spent much of his time in it, and in 1814-15 published his *Bibliotheca Spenceriana*. In 1818 he was commissioned by Earl Spencer to purchase books for him on the continent of Europe, an expedition described in his sumptuous *Bibliographical, Antiquarian and Picturesque Tour in France and Germany* (1821). Dibdin was the originator and vice president of the Roxburghe club, founded in 1812.

Other works of his are *Bibliomaniacs* (1809), *Reminiscences of a Literary Life* (1816), and *Bibliographical, Antiquarian and Picturesque Tour in the Northern Counties of England and Scotland* (1833).

DIBDIN, THOMAS JOHN (1771-1841), English dramatist and song writer, son of Charles Dibdin, the song writer, the composer of "Tom Bowling," was born on March 21, 1771.

He was apprenticed to his maternal uncle, a London upholsterer, and later to William Rawlins, afterwards sheriff of London, from whose service he ran away to join a company of country players. He returned to London in 1705, having married two years before, and in the winter of 1708-9 his *Law and the Doctor* was produced at Covent Garden. His 70 comedies, operas and farces brought immense popularity to the writer and immense profits to the theatres. It is stated that the pantomime of *Mother Goose* (1807) produced over £20,000 for the management at Covent Garden theatre, and *The High mettled Racer*, adapted as a pantomime from his father's play, £18,000 at Astley's. Dibdin was prompter and pantomime writer at Drury Lane until 1816, when he took the Surrey theatre. This venture proved disastrous. After this he was manager of the Haymarket, but without his old success, and his last years were passed in comparative poverty. In 1827 he published two volumes of *Reminiscences*. Of his songs "The Oak Table" and "The Snug Little Island" are well known. He died in London on Sept. 16, 1841.

See *Reminiscences of Thomas Dibdin* (1827), and F. R. Dibdin *The Dibdins* (1888).

DIBRA (Serbian *Debar*), a fortified city in S. Serbia, Yugoslavia, and the key to the upper valley of the Black Drin. Pop. (1931) 6,913, of Albanians, Bulgars and Serbs. There are two Serbian schools. Cattle breeding is the chief occupation but some maize and tobacco are grown. There are sulphurous springs in the neighbourhood. It was captured by the Serbs in the Balkan Wars (1912-13) and assigned to them by the Treaty of Bucharest (1913). It was occupied by Bulgaria in 1941.

DIBRUGARH, a town of British India, headquarters of the Lalumpur district of Assam, on the Dibru river about 4 m. above its confluence with the Brahmaputra. Pop. (1941) 13,191. It is the terminus of steamer navigation on the Brahmaputra, and also of a railway line, which connects with the Assam Bengal system. The town contains a cantonment, the headquarters of the Assam Valley Light Horse and various educational institutions. In 1900 a medical school was established from a bequest by J. Berry White, to train hospital assistants for the tea gardens.

DICAEARCHUS, of Messene in Sicily, Peripatetic philosopher and pupil of Aristotle, historian, and geographer, flourished about 320 B.C. He was a friend of Theophrastus, to whom he dedicated many of his works. Of his writings only the titles and a few fragments survive. The most important of them was his *βίος τῆς Ελλάδος* (*Life in Greece*), in which the moral, political, and social condition of the people was fully discussed. In his *Τρηπτόλικος* he described the best form of government as a mixture of monarchy, aristocracy, and democracy, and illustrated it by the example of Sparta. Among the philosophical works of Dicaearchus may be mentioned the *Λεσβιακός*, a dialogue in three books, showing that the soul is mortal, to which he added a supplement called *Korinthiakos*. He also wrote a *Description of the World*, illustrated by maps, in which was probably included his *Measurements of Mountains*. A description of Greece (150 iambics, in C. Muller *Frags. Hist. Graec.* 1: 238-243) was formerly attributed to him, but was really the work of Dionysius, son of Calliphon. The *De republica* is supposed to be founded on one of Dicaearchus's works.

The best edition of the fragments is by M. Fuhr (1841), a work of great learning; see also a dissertation by F. G. Osnab, *Beiträge zur nord- und griech. Literatur*, II pp. 1-117 (1839), Pauli-Wissowa, *Realencyklopädie der class. Altertumswiss.*, v pt. 1 (1905).

DICE, small cubes of ivory, bone, wood or metal used in gaming (O Fr. *de*, derived from Lat. *dare*, to give). The six sides of a die are each marked with a different number of incised dots in such a manner that the sum of the dots on any two opposite sides shall total seven. Dice seem always to have been employed, as they still are, for gambling, and in games like backgammon. There are many methods of playing, from one to five dice being used, the dice being thrown on to a smooth surface either from the hand or dice-box.

It is a remarkable fact that, wherever dice have been found, whether in the tombs of ancient Egypt, of classic Greece, or of the far East, they differ in no material respect from those in use

to day, the elongated ones with rounded ends found in Roman graves having been not dice but *tabulae*, or knucklebones. Eight-sided dice have comparatively lately been introduced in France as aids to children in learning the multiplication table. The tetrahedron, or spinning die, used in many modern games, was known in ancient times in China and Japan.

The increased popularity of the more elaborate forms of gaming has resulted in the decline of dicing. One method is to throw three

FIG. 1. COPIES OF SIX-SIDED EARLY EGYPTIAN DICE AND TWO ROMAN DICE.

SIX SIDED EARLY EGYPTIAN DICE AND TWO ROMAN DICE.

Dice similar to those used to day have been found among ancient relics in Egypt, the Mediterranean and the Far East.

times with three dice. If one or more sixes or fives are thrown the first time, they may be reserved, the other throws being made with the dice that are left. The object is to throw three sixes=18 or as near that number as possible.

The most popular form of pure gambling with dice at the present day is *craps*, or *crap shooting*, a simple form of *hazard*, of French origin. Two dice are used. Each player puts up a stake and the first player may cover any or all of the bets. He then "shoots," i.e., throws the dice from his open hand upon the table. If the sum of the dice is 7 or 11 the throw is a *nich*, or *natral*, and the player wins all stakes. If the throw is either 2, 3 or 12 it is a *crap*, and the player loses all. If any other number is thrown it is a *point*, and he continues until he throws the same number again, in which case he wins, or a 7, in which case he loses. *Poker dice* are marked with ace, king, queen, jack, ten and nine spot. Five are used and the object is, in three throws, to make pairs, triplets, full hands or fours and fives of a kind, five aces being the highest hand. Straights do not count.

History—Dice were probably evolved from knucklebones. The antiquary Thomas Hyde, in his *Syntagma*, records his opinion that the game of "odd or even," played with pebbles, is nearly coeval with the creation of man. It is almost impossible to trace clearly the development of dice as distinguished from knucklebones, on account of the confusing of the two games by the ancient writers. It is certain, however, that both were played in times antecedent to those of which we possess any written records. Sophocles, in a fragment, ascribed their invention to Palamedes, a Greek, who taught them to his countrymen during the siege of Troy, and who, according to Pausanias (on Corinth, xx), made an offering of them on the altar of the temple of Fortune. Herodotus (*Clio*) relates that the Lydians, during a period of famine in the days of King Atys, invented dice, knucklebones and indeed all other games except chess. The fact that dice have been used throughout the Orient from time immemorial, as has been proved by excavations from ancient tombs, seems to point clearly to an Asiatic origin. Dicing is mentioned as an Indian game in the *Rig veda*. In its primitive form knucklebones was essentially a game of skill, played by women and children, while dice were used for gambling, and it was doubtless the gambling spirit of the age which was responsible for the derivative form of knucklebones, in which four sides of the bones received different values, which were then counted, like dice.

Gambling with three, sometimes two, dice (*κίβοι*) was a very popular form of amusement in Greece, especially with the upper classes, and was an almost invariable accompaniment to the symposium, or drinking banquet. The dice were cast from conical beakers, and the highest throw was three sixes, called *Aphrodite*, while the lowest, three aces, was called the *dog*. Both in Greece

and Rome different modes of counting were in vogue. Roman dice were called *lesserae* from the Greek word for four, indicative of the four sides. The Romans were passionate gamblers, especially in the luxurious days of the empire, and dicing was a favourite form though it was forbidden except during the Saturnalia. The emperor Augustus wrote in a letter to Suetonius concerning a game that he had played with his friends: "Whoever threw a *dog* or a six paid a *denarius* to the bank for every die, and whoever threw a *Venus* (the highest) won every thing." In the houses of the rich the dice-bearers were of carved ivory and the dice of crystal inlaid with gold. Mark Antony wasted his time at Alexandria with dicing, while, according to Suetonius, the emperors Augustus, Nero and Claudius were passionately fond of it, the last named having written a book on the game. Caligula notoriously cheated at the game, Domitian played it, and Commodus set apart special rooms in his palace for it. The emperor Verus, adopted son of Antoninus, is known to have thrown dice whole nights together.

Fashionable society followed the lead of its emperors, and, in spite of the severity of the laws, fortunes were squandered at the dicing table. Horace derided the youth of the period, who wasted his time amid the dangers of dicing instead of taming his charger and giving himself up to the hardships of the chase. Throwing dice for money was the cause of many special laws in Rome, according to one of which no suit could be brought by a person who allowed gambling in his house, even if he had been cheated or assaulted. Professional gamblers were common, and some of their loaded dice are preserved in museums. The common public-houses were the resorts of gamblers, and an old fresco is extant showing two quarrelling dicers being ejected by the indignant host. That the barbarians were also given to gaming, whether or not they learned it from their Roman conquerors, is proved by Tacitus, who states that the Germans were passionately fond of dicing, so much so, indeed, that, having lost everything, they would even stake their personal liberty. Centuries later, during the middle ages, dicing became the favourite pastime of the knights, and both dicing schools (*scholae decarum*) and guilds of dicers existed. In France both knights and ladies were given to dicing, which repeated legislation did not abolish. In India and

more or less cultivated. Other noteworthy American species are the Dutchman's breeches (*D. cucullaria*), one of the most attractive wild flowers of eastern North America, the squirrel corn (*D. canadensis*), of similar range, the small tubers of which resemble grains of Indian corn (maize), and the golden ear drops (*D. chrysanthia*), a smooth, stiff stemmed plant, 2 ft. to 5 ft. high, with large pancelled clusters of yellow flowers, widely distributed in California. (See DUTCHMAN'S BREECHES.)

DICETO, RALPH DE (d. c. 1202), dean of St. Paul's, London, and chronicler, is first mentioned in 1152, when he received the archdeaconry of Middlesex. He was probably born between 1120 and 1130, of his parentage and nationality nothing is known. Diceto was selected, in 1166, as the envoy of the English bishops when they protested against the excommunications launched by Becket. About 1180 he became dean of St. Paul's. In this office he distinguished himself by careful management of the estates, by restoring the discipline of the chapter, and by building at his own expense a deanery house. Diceto's most important historical works, the *Abbreviationes Chroniconum* and the *Ymagines Historiarum*, cover the history of the world from the birth of Christ to the year 1202. The former, which ends in 1147, is a work of learning and industry, but almost entirely based upon extant sources. The latter, beginning in a compilation from Robert de Monte and the letters of Foliot, becomes an original authority about 1172, and a contemporary record about 1181. The *Ymagines* is a valuable authority for the last years of the reign of Henry II and for the reign of Richard I.

See the introduction to W. Stubbs's edition of the *Historical Works* of Diceto (Rolls ed. 1876, 2 vols.). Diceto's fragmentary Domesday of the capital estates has been edited by Archdeacon Hale in *The Domesday of St. Paul's*, pp. 109 ff. (Camden Society, 1858).

DICEY, EDWARD (1832-1911), English writer, son of T. E. Dicey of Claybrook Hall, Leicestershire, was born on May 15, 1832, and educated at Trinity college, Cambridge, where he took mathematical and classical honours. He visited the United States in 1862, and in 1863 wrote *Six months in the Federal States*, in which he took the part of the North. He was called to the bar in 1875, became a bencher of Gray's Inn in 1896, and was treasurer 1893-04. He was connected with the *Daily Telegraph* from 1862 onwards as leader writer and then as special correspondent, and after a short spell in 1870 as editor of the *Daily News*, he became editor of the *Observer*, a position which he held for 19 years. Of his many books on foreign affairs perhaps the most important are his *England and Egypt* (1884), *Bulgaria, the Peasant State* (1895), *The Egypt of the Future* (1907). He died in London on July 7, 1911.

His brother ALBERT VENN DICEY (1835-1922), English jurist, was educated at Balliol college, Oxford, and was called to the bar at the Inner Temple in 1863. He held fellowships successively at Balliol, Trinity and All Souls', and from 1882 to 1900 was Vinerian professor of law. He became QC in 1890. His chief works are the *Introduction to the Study of the Law of the Constitution* (1885, 6th ed. 1902), a standard work on the subject, *England's Case against Home Rule* (1886), *A Digest of the Law of England with Reference to the Conflict of Laws* (1896), and *Lectures on the Relation between Law and Public Opinion in England during the 19th century* (1905). He died on April 7, 1922.

DICHOTOMY, literally a cutting asunder, the technical term for a form of logical division, consisting in the separation of a class into two sub-classes, one of which has and the other has not a certain quality or attribute (Gr. *di* = apart, *chōreō* = to cut). Men may be thus divided into white men and men who are not white, each of these may be subdivided similarly. On the principle of contradiction this division is both exhaustive and exclusive, there can be no overlapping, and no members of the original genus or the lower groups are omitted. This method of classification, though formally accurate, has slight value in the exact sciences, partly because at every step one of the two groups is merely negatively characterized and may be unreal, it is useful, however, in setting forth clearly the gradual descent from the most inclusive genus (*summus genus*) through species to the lowest class (*infima species*), which is divisible only into individ-

vol. 1, pp. 243-4)

North American Indians are said to have played dice as far back as 1536. In his revelations of the time, Father Brebeuf gives long accounts of the game, the causes for its being played and the excesses in gambling to which it led. Even up to about 1860, the Indians were known to stake all they had, frequently losing all their earthly possessions. Dice or *Crap* was a popular game among the American soldiers in France during World War I, the Afro-Americans possessing a marked fondness for the "bones."

DICENTRA, a genus of perennial herbs of the fumitory family (Fumariaceae), containing 15 species, natives of Asia and North America, 8 of which occur in the United States and Canada. They are mostly low or stemless plants, a few of which are cultivated for their attractive deeply cut or dissected foliage and handsome irregular flowers. The familiar bleeding-heart (*D. spectabilis*) of the gardens, with showy rose-red, heart-shaped flowers, an inch or more long, is a native of Japan. The eastern bleeding-heart (*D. eximia*), with pink, narrow, heart-shaped flowers, about 2 in. long, of the Allegheny Mountain region, and the western bleeding heart (*D. formosa*), with similar rose-purple flowers, of mountain woods from California to British Columbia, are both

ual persons or things (*See* DIVISION) In astronomy the term is used for the aspect of the moon or of a planet when apparently half illuminated, so that its disc has the form of a semicircle

DICK, ROBERT (1811-1866), Scottish geologist and botanist, was born in Tullibody, Clackmannanshire, the son of an officer of excise. He became a baker and worked at his trade until his death in Thurso on Dec. 24, 1866. He never published any thing, but from 1835 onwards, when he first discovered fossils in the Caithness flags, he sent his specimens to Hugh Miller and others. His herbarium, which consisted of about 200 folios of mosses, ferns and flowering plants, is now stored, with many of his fossils, in the museum at Thurso

DICKCISSEL (*Spiza americana*), a common North American bird between the Rockies and the Alleghenies from Minnesota and western Ontario southward. It is recognized by its yellow breast, wing-band, sides of throat and eye streak, and is slightly over 6 in. long. It is brownish in colour, with chestnut shoulders, and the black crescent at the bottom of its white throat gives it the name of black-throated hunting

DICKENS, CHARLES JOHN HUFFAM (1817-1870) the most popular and perhaps the greatest of English novelists, was born on Feb. 7, 1812 in Landport, a division of Portsea, in a house in Mile End terrace, Commercial road. The house can be identified and is in some sense a popular shrine or memorial, enabling the sightseer to link up in one journey two of the most romantic national names, associating Dickens with Portsea and Nelson with Portsmouth. But beyond this symbolic and almost legendary local interest, the actual address indicates little more than the drifting and often decaying fortunes of the class and family from which he came. It would be an exaggeration to compare it to Laus street, in the Borough, of which, it will be remembered, "the inhabitants were migratory, disappearing usually towards the verge of quarter day." But there is the note of something nomadic about the social world to which he belonged. We talk of the solid middle class, he belonged, one might almost say, to the liquid middle class, certainly to the insecure middle class. His father, John Dickens, was a clerk in the Navy Pay Office, and all through life a man of wavering and unstable status, partly by his misfortunes and partly by his fault. It is said that Dickens sketched him in a lighter spirit as Micawber and in a sadder and more realistic aspect as Dorrit. The contrast between the two men, as well as the two moods, should be a warning against the weakness of taking too literally the idea of Dickensian "originals." The habit has done grave injustice to many people, such as Leigh Hunt, and it may involve a grave injustice to John Dickens, and perhaps an even graver injustice to Mrs. John Dickens, nee Elizabeth Barrow, whom a similar rumour reports as the real Mrs. Nickleby. Some may question, not without grief, whether there really could be a real Mrs. Nickleby. But in any case there certainly could not be a man who was both Dorrit and Micawber. The truth is that we shall misunderstand from the beginning the nature of the Dickensian imagination, if we suppose these things to be mechanical portraits in black and white, taken by "the professed machine," as Mr. Weller said. It is the whole point of Dickens that he took hints from human beings, and turned them, one may say, into superhuman beings. But it is true that John Dickens was of the type that is often shifted from place to place, and this is the chief significance of Charles Dickens's connection with Portsea, or rather of his lack of connection with it. He can only have been two years old when the household moved for a short time to London and then for a longer time to Chatham. It was perhaps lucky that the formative period of his first childhood was also the most fortunate period of his not very fortunate family. The dockyard of Chatham, the towers of Rochester, the

greater profit, from a random heap of old novels that included much of the greatest English literature and even more of the type of literature from which he could learn most, *Roderick Random* and *Robinson Crusoe* and *Tom Jones* and *The Vicar of Wakefield*

He can hardly have been ten years old when the household was once more upon the march. John Dickens had fallen heavily into debt, he continued the tendency to change his private address, and his next private address was the Debtors' Prison of the Marshalsea. His wife, the mother of eight children of whom Charles was the second, had to encamp desolately in Camden Town and open a dingy sort of "educational establishment." Meanwhile the unfortunate Charles was learning his lessons at a very different sort of educational establishment. After helping his mother in every sort of menial occupation, he was thrown forth to earn his own living by tying and labelling pots of blacking in a blacking warehouse at Old Hungerford Stairs. The blacking was symbolic enough, Dickens never doubted that this piece of his childhood was the darkest period of his life, and he seems indeed to have been in a mood to black himself all over, like the Ohello of the Crummles Company. Of his pessimistic period, of the heartrending monotony and ignominy, he has given little more than a bitter abbreviation in *David Copperfield*. But he had stored up much more than bitterness, it is obvious that he had already developed an almost unquenchable vigilance and alertness of attention. By the time his servitude came to an end, by his father filing into a legacy as he had fallen into a jail (there was really a touch of Micawber in him) the boy was no longer a normal boy, let alone a child. He called his wandering parent "the Prodigal Father", and there was something of the same fantastic family inversion in the very existence of so watchful and critical a son. We are struck at once with an almost malicious maturity of satire, some of the best passages of the prison life of the Pickwick and the Dorrits occur in private letters about his own early life. He had shared, of course, the improvement in the family condition, which was represented in his case by a period of service as a clerk to a Mr. Blackmore, a Grays Inn solicitor, and afterwards in the equally successful, and much more congenial, occupation of a newspaper reporter and ultimately a Parliamentary reporter. His father had taken up the trade, but his son was already making a mark in it, as reporter to *The True Sun*, *The Mirror of Parliament* and *The Morning Chronicle*. In all these aspects and attitudes, at this time, he appears as alert, sharp-witted and detached, recalling that sort of metallic brightness which an observer at this period so often saw flash upon his face. It is worthy of note, because certain healthy social emotions which he always championed have somewhat falsified his personality in the eyes of the pious whom he loved to rap over the head. He was a genuine champion of gentility, but he was not always genial, certainly not only genial. One of his earliest sketches, published not long after this time, was a defence of the Christian festivity of Christmas against the Puritans and the Unitarians, it was called "Sunday Under Three Heads." All his life he defended valiantly the pleasures of the poor, and insisted that God had given ale and rum, as well as wine, to make glad the heart of man. But all this has clouded his character with fumes of mere conviviality and irresponsibility which were very far from being really characteristic. Even in youth, which is the period of irresponsibility, Dickens appears in some ways as highly responsible. He was in sharp reaction against the futility of his family, he was both ambitious and industrious, and there were some who even found him hard. In many moods he had as angry a dislike of the Skimpoles as of the Gradgrinds.

Indeed he had come in more ways than one to the high turning-point of his fortunes. His marriage and his first real literary work can be dated at about the same time. He had already begun to write sketches, chiefly in *The Old Monthly Magazine*, which were in the broadest sense caricatures, of the common objects of the street or the market place. They were illustrated by Cruikshank, and in these early stages of the story the illustrator is often more important than the author. This was notoriously true of his next

and perhaps his greatest experiment, but it is typical in any case of his time and his time of life. The prose sketches were signed "Boz" and the signature had become a recognized pseudonym when Messrs Chapman and Hall, the publishers, approached him with the suggestion of a larger scheme. A well known humorous artist of that epoch, Seymour, was to produce a series of plates illustrating the adventures, or misadventures, of the Nimrod Club, a group of amateur sportsmen, destined to dwindle and yet to grow infinitely greater in the single figure of Mr Nathaniel Winkle. Dickens consented to write the letter press, which was little more than a running accompaniment like an ornamental border around the drawings, and in that strange fashion, secondary, subordinate and even trivial, first formed itself in the human fancy the epic and pantomime of *Pickwick* (1837). Dickens persuaded the publishers to let the Pickwick Club represent more varied interests or eccentricities retained Mr Winkle to represent or misrepresent the original notion of sport, and by that one stroke of independence cut himself free from a stale fashion and started a new artistic adventure and revolution. He gave as one of his reasons the fact that he had no special knowledge of sports or games, and proceeded to drive his argument home triumphantly by his description of the cricket-match at Dingley Dell. And yet that cricket-match alone might illustrate exactly the game which Dickens so gloriously won, and why that wild and ill-instructed batsman had so many thousand runs and is not out. What did a few mistakes in the description of cricket, or even in the description of real life, matter in a man who could invent that orator at the cricket dinner, who complimented the defeated eleven by saying, with the gesture of Alexander, "If I were not Dumkins, I would be Luffey, if I were not Podder, I would be Struggles"? Men do not read that sort of thing to learn about cricket, or even about life, but to find something more living than either. There had broken through the entanglements of that trumpery bargain a force of comic genius which swallowed up its own origin and excuses, a wild animal big enough to eat all its direction labels. People forgot about Seymour, forgot about sport, forgot about the Nimrod Club, soon forgot about the Pickwick Club. They forgot all that he forgot and followed whatever he followed, much bigger and wider game than any aimed at by the mere gun of Mr Winkle. The track of the story wandered, the tone of the story changed, a servant whom Pickwick found cleaning boots in an inn-yard took the centre of the stage and towered even over Pickwick, Pickwick from being a pompous buffoon became a generous and venerable old English gentleman, and the world still followed that incredible transformation scene and wishes there were more of it to this day. This was the emergence of Dickens into literature. It had, of course, many secondary effects in life. One was the first and almost the most bitter of his quarrels, Seymour may be excused for having been annoyed at the relations of artist and author being thus turned upside down in a whirlwind, but Seymour was not therefore necessarily justified in saying, as he did say and his widow long continued to say, that Dickens had gained glory from another man's ideas. Nobody, we may well imagine, believes that the oration of Sergeant Buzfuz or the poem of Mrs Leo Hunter, were Mr Seymour's ideas. Dickens had an inexhaustible torrent of such ideas, and no man on earth could pretend to have provided them. But it is true that in this quarrel, as in others, some found a touch of sharpness and acid self defence in Dickens, and he was never without his enemies. His ideal was certainly the leisure and geniality of Pickwick, but he was fighting rather too hard for his own hand and had too much at stake and too pressing a knowledge of poverty to be anything but practical.

As Pickwick was the foundation of his public life, his marriage was naturally the foundation of his private life, and in this also he has been an object of criticism as he was certainly an object of sympathy. Very little good is done by making guesses about a story of which the spiritual balance and proportion were probably never known to more than three or four people. It is sufficiently significant that those who were nearest to it, and who survive to speak or rather to be silent, agree in laying no very heavy blame upon anyone involved. One of the principals of the

Morning Chronicle, George Hogarth, had been so much struck by the "Boz" sketches as to insist on an improvement in the payment of the writer, he introduced Dickens to his family and especially (we may say) to his daughters, with all of whom the young journalist seems to have been on very friendly and even affectionate terms. One of them, Catherine, he married, and certainly married for love, but not perhaps with the sort of love which gives a man a full and serious realization of what he is doing. It is the ethos of the story that in a sense the friendship outlasted the love, for another sister, who understood him better, remained his friend long after his marriage had become a prolonged misunderstanding. All this, however, happened long afterwards, for the moment his marriage may be taken as marking his step into security and success, especially as he was probably stimulated and, it were, intoxicated, by a romance that brought him into more refined social surroundings than his own. From that moment he was launched as a popular writer and a power in the world, and he never went back, until he died of popularity thirty years afterwards.

It is notable that his next work was *Oliver Twist* (1838), which might be meant for a contrast to *Pickwick*. If the first trick had succeeded, nobody could accuse the conjurer of trying the same trick twice. He was probably proud of proving his range, but he was certainly courageous in testing his popularity. It is true that *Oliver Twist* consists of a queer mixture of melodrama and realism, but both the realism and the melodrama are deliberately dark and grim. Nevertheless it is fortunate that with his second book he thus brought into play what may be called his second talent. It is too common to compare his humour with his pathos, for indeed there is no comparison. But there really is a comparison between his humour and his horror, and he really had a talent for a certain sort of horror, which is evocatively rendered by the popular phrase of supping on horrors. For there is a sort of lurid conviviality that accompanies the panic, as if the nightmare could accompany and not follow the heavy meal. Thus suppressed vitality is due to his never for an instant losing the love of life, the love of death, which is despair and pessimism, was meaningless to him till he died. The sort of horror which afterwards conceived the death of Krook is already found in *Oliver Twist*, as "in that intolerable repetition throbbing in the murderer's ears, 'will wash out mud-stains, blood stains'" and so on. For the rest, the plot is preposterous and the flashes of fun excellent but few, yet there is another aspect of the book which makes it important in the story of Dickens. It is not only the first of his nightmare novels, but also the first of his social tracts. Something of social protest could be read between the lines of *Pickwick* in prison, but the prison of *Pickwick* was very mild compared with the charitable almshouse of *Oliver*. Dickens is witness, with Hood and Cobbett and many others, that the workhouse was felt by all generous people as something quite unnaturally new and hard and inhuman. It is sometimes said that he killed Bumble, it would be truer to say that, by making Bumble live, he created something by which it will always be possible to kill bureaucracies.

Whether we call the transition from *Pickwick* to *Oliver Twist* a change from comedy to tragedy, or merely a change from farce to melodrama, it is notable that the next act of Dickens is to mix the two in about equal proportions. Having shown how much he can vary, he tries to show how well he can combine. It is worth noting because it explains much of the failure as well as the success of his art as a whole. We may even say that, to the last, this sort of exhibition of power remained his principal weakness. When the critics, like those of *The Quarterly*, called him vulgar, it meant nothing except that the critics themselves were snobbish. There is nothing vulgar about drinking beer or describing the drinking of beer, or enjoying the humours of really humorous people who happen to black boots, like Sam Weller. But there is something just a little vulgar about professing to be a Universal Provider, a man who writes not only something that he wants to write, but anything that anybody wants to read. Anything in his work that can really be called failure is very largely due to this appetite for universal success. There is nothing

wrong about the jester laughing at his own jokes, indeed they must be very poor jokes if even he cannot laugh at them. Dickens, in one of those endless private letters which are almost more entertaining than his published novels, describes himself as "a gentle man with rather long hair and no neckcloth, who writes and grins, as if he thought he was very funny indeed", and so he was. But when he set out to prove that he was not only very funny, but very pathetic, very tragic, very powerful, he was not always enjoying the sense of power over his work, he was enjoying the sense of power over his audience. He was an admirable actor in private theatricals, and sometimes, unfortunately, they were public theatricals. And on this side of his character he had the proverbial itch of Toole to act Hamlet. When he was rendering the humours of the crowd, he was that rather rare thing, a real democrat. But when he was trying to command the tears and thrills of the crowd, he was something of a demagogue, that is, not one mingling with the crowd but one trying to dazzle and to drive it. One of the ways in which he displayed this attribute, if not of vulgarity at least of vanity, was in his habit, from this time onwards, of running side by side in the same book about five different stories in about five different styles. It pleased the actor in him to show his versatility and his ease in turning from one to the other. He did not realize clearly enough that in some of the parts he was a first-rate actor and in some a second rate, and in some a fifth-rate actor. He did not remind himself that though he turned to each topic with equal ease, he did not turn to each with equal effect. But, whatever the disadvantages of the universal ambition, it definitely dates from the period of his next book. *Pickwick* has a prevailing tint of gaiety and *Oliver Twist* of gravity, not to say grimness, but with *Nicholas Nickleby* (1839) we have the new method, which is like a pattern of bright and dark stripes. The melodrama is if possible even more melodramatic than in *Oliver Twist*, but what there is of it is equally black and scowling. But the comedy or farce has already displayed the rapid ripening of his real genius in letters. There is no better company in all literature than the strolling company of Mr. Vincent Crummles, though it is to be hoped that in any convivial meeting of it, Miss Snevlicci will remember to invite her incomparable papa. Mr. Mantalini also is one of the great gifts of Dickens to the enduring happiness of humanity. For the rest, it is very difficult to take the serious part of the story seriously. There is precious little difference between the rant and claptrap of the Crummles plays, which Dickens makes fun of, and the rant and claptrap of Ralph Nickleby and Mulberry Hawke which Dickens gravely narrates to us. All that, however, was of little consequence either immediate or permanent. Dickens was not proving that he could write smooth and probable narratives, which many people could do. He was proving that he could create Mantalini and Snevlicci, which nobody could do.

Nevertheless, this pretence of providing for all tastes, which produced the serio-comic novel, is also the explanation of the next stage of his career. There runs or recurs throughout his whole life a certain ambition to preside over a more or less complex or many-sided publication, a large framework for many pictures, a system of tales within tales like the Arabian Nights or the tales of the Tabard. It is the ambition that he afterwards gratified by becoming the editor of two magazines, *Household Words* and *All the Year Round*. But there is here something of a shadow of the original meaning of the word magazine, in the sense of a shop, and another hint of that excessive desire to keep a shop that sells everything. He had been for a time editor of something of the sort in *Bentley's Miscellany*, but the final form taken by this mild and genial megalomania (if we may so describe it) was the plan which Dickens formed immediately after the success of *Nicholas Nickleby*. The serial scheme was to be called, "Master Humphrey's Clock," and was to consist of different stories told by a group of friends. With the idea of making them the more friendly he turned some of them into old friends, reintroducing Mr. Pickwick and the two Wellers, though these characters were hardly at their best, the author's mind being already on other things. One of these things was a historical novel, perhaps conceived more in the romantic manner of Scott than the prosaic

manner of Smollett, which Dickens generally followed. It was called *Barnaby Rudge* (1840) and the most interesting part of it perhaps is the business of the Gordon Riots, and the mob that has a madman for its mascot and a penny dreadful pretence for its comic relief. But there is also a plot as complicated as, though rather clearer than, that of *Oliver Twist*, a plot that intensely interested the detective mind of Poe. *Barnaby Rudge*, however, is not so directly Dickensian as the romance that preceded or the romance that followed it. The second story, somewhat insecurely wedged into the framework of *Master Humphrey's Clock*, was *The Old Curiosity Shop* (1841), as the opening and some of the references in the story still vaguely attest. The public reception of this story very sharply illustrates what has been said about the double character of his success. On the one side was his true success as a craftsman carving figures of a certain type, generally gargoyles and grotesques. On the other side was his inferior success as a jack of all-trades tending only too much to be a cheap jack. As a matter of fact, *The Old Curiosity Shop* contains some of the most attractive and imaginative humour in all his humorous work, there is nothing better anywhere than Mr. Swiveller's imitation of the brigand or Mr. Brass's formal oration over the dwarf. But in general gossip and association, everything else in the story is swallowed up in the lachrymose subject of Little Nell. There can be no doubt that this unfortunate female had a most unfortunate effect on Dickens's whole conception of his literary function. He was flattered because silly people wrote him letters imploring him not to let Little Nell die, and forgot how many sensible people there were, only hoping that the Marchioness would live for ever. Little Nell was better dead, but she was an unconscious long time dying, and we cannot altogether acquit Dickens of keeping her lingering in agony as an exhibition of his power. It tended to fix him in that unfortunate attitude, of something between a showman and a magician, which explains almost all the real mistakes of his life.

About this time a very determining event interrupted his purely literary development, his first visit to America. It was destined to have, apart from any other results, a direct effect upon his next book, which was *Martin Chuzzlewit* (1844). There were, of course, many purely practical and personal elements in the criticism which he directed against the western democracy. An unjust copyright law, or one which he at any rate thought very unjust, had enabled Americans to pirate his most popular works, and it would seem that the people he met were, in their breezy way, but little inclined to apologize for the anomaly. But it would be very unjust to Dickens to deny that his sense and sensibility were alike irritated by some real divisions in the international relation. There were things in the American culture, or lack of culture, which he could not be expected to understand but which he might reasonably be expected to dislike. His English law-abiding liberalism would in any case have been startled by a certain streak of ferocity and persecution that there really is in the Americans, just as he might have recoiled from the same fierceness in the Irish or the Italians. But in the Americans it was also connected with something crude and incomplete in the society, and was not softened by tradition or romance. He was also both annoyed and amused at the American habit of uttering solemn idealistic soliloquies and of using rhetoric very rhetorically. But all these impressions are important chiefly as they changed the course of his next important narrative, and illustrated a certain condition or defect of his whole narrative method.

All these early books of Dickens, from *Pickwick* onward, appeared, it must always be remembered, serially and in separate parts. They were anticipated eagerly like bulletins, and they were often written up to time almost as hastily as newspaper reports. One effect of this method was that it encouraged the novelist in a sort of opportunism and something of a hand to mouth habit of work. And a character that always belonged, in varying degrees, to his novels is first and most sharply illustrated in *Martin Chuzzlewit*. The earlier numbers, though they contained the two superb caricatures called Pecksniff and Mrs. Gamp, had not for some reason been so popular as the caricatures called Pickwick and Miss Squeers. Dickens was already beginning

to show something of that feverish fatigue which was the natural reaction of his fervid industry. He feared that the public was bored with the book, he became perhaps subconsciously a little bored with it himself. He conceived the bold idea of breaking the story in the middle and putting in a purple patch woven from his wild memories of the Yankees. It was completely successful, in the comedy sense, but it is worth noting that Dickens did something curiously Dickensian in thus suddenly sending Martin Chuzzlewit across the sea to America. It is not easy to imagine Thackeray suddenly hurling Pennicums from Mayfair into the middle of Australia, or George Eliot dislodging Felix Holt and flinging him as far as the North Pole. The difference was partly the result of the Dickensian temper and partly of the method of publication. But it will be well to remember it for there is more than one example of what looks like a positive change of plan in the Dickens stories, made more possible by this early habit of not producing the work of art as a whole. Some have suggested that the degeneration of Boffin was originally meant to be real, and his rather clumsy plot an afterthought. And the same idea has figured in the reconstructions of *Edwin Drood*.

At this point there is a break in the life of Dickens, in more ways than one. It is represented by his decision to live abroad for a time, chiefly on grounds of economy, the last lingering results of the relative failure of *Martin Chuzzlewit*. He took a villa in the neighbourhood of Genoa in 1844, and he and his family, already a fairly large one, settled down there with a certain air of finality that deserved for a time the name of exile. But it is curious to note that the literary work done there has something of the character of an interlude, and indeed of a rather incongruous interlude. For it was in that Italian landscape that he concentrated on a study so very domestic, insular and even cockney as *The Chimes* (1845), and industriously continued the series of short Christmas stories which had recently begun in the very London fog of *A Christmas Carol* (1843). Whatever be the merits or demerits of the *Christmas Carol*, it really is a carol, in the sense of being short and direct and having the same chorus throughout. The same is true in another way of *The Chimes*, and of most things that occupied him in his Italian home. He had not settled down to another long and important book, and it soon became apparent that he had not settled down at all. He returned to London, the landscape which for him was really the most romantic and even historic, and did something so ominously typical of the place and time as almost to seem like tempting Providence. He became the first editor of the *Daily News*, a paper started to maintain those Liberal, if not Radical opinions of which he always shared the confident outlook and the humane simplicity. He did not long remain attached to the editorial chair or even to the metropolis, for this was the most restless period in all his restless life. He immediately went back to Lausanne and immediately wanted to go back to London. It seems probable that this break in his social life corresponded to a break in his artistic life which was in a sense just about to begin all over again and begin at the other end. He did indeed write one more full size novel of the earlier type, *Dombey and Son* (1846-48); but it has very much the character of the winding up of an old business, like the winding up of the Dombey firm at the end of it. It is comic as the earlier books were comic, and no praise can be higher, it is conventional as the earlier plots were conventional, and never really pretended to be anything else, it contains a dying child upon the pattern of Little Nell, it contains a very amusing major much improved from the pattern of Mr Dowler. But underneath all this easy repetition of the old dexterity and the old clumsiness the mind of the conjurer is already elsewhere. *Dombey and Son* was more successful in a business sense than *Martin Chuzzlewit*, though really less successful in many others. Dickens settled again in England in a more prosperous style, sent his son to Eton and, what was more sensational, took a rest. It was after a long holiday at Broadstairs, in easier circumstances more favourable to imaginative growth and a general change of view, that there appeared in 1850 an entirely new novel in an entirely new style.

There is all the difference between the life and adventures of

David Copperfield and the life and adventures of Nicholas Nickleby, that there is between the life of Charles Dickens and the life of Amadis of Gaul. The latter is a good or bad romance, the former is a romantic biography, only the more realistic for being romantic. For romance is a very real part of life and perhaps the most real part of youth. Dickens had turned the telescope round or was looking through the other end of it, looking perhaps into a mirror, looking in any case out of a new window. It was life as he saw it, which was somewhat fantastically, but it was his own life as he knew it, and even as he had lived it. In other words, it is fanciful but it is not fictitious, because not merely invented in the manner of fiction. In Pickwick or Nickleby he had in a sense breathed fresh imaginative life into stock characters, but they were still stage characters, in the new style he may be extravagant, but he is not stagey. That vague glow of exaggeration and glamour which he has over all the opening chapters of *David Copperfield*, which dilates some figures and distorts others, is the genuine sentimentalism and suppressed passion of youth, it is no longer a convention or tradition of caricature. There are men like Steerforth and girls like Dora, they are not as boys see them, but boys do see them so. This passionate autobiography, though it stiffens into greater conventionality at the real period of passion, is really, in the dimly battered phrase, a human document. But something of the new spirit, more subtle and sympathetic but perhaps less purely creative, belongs to all the books written after this date. The next of the novels in point of time was *Bleak House* (1853), a satire chiefly directed against Chancery and the law's delay, but containing some brilliant satire on other things, as on the philanthropic fool whose eyes are in the ends of the earth. But the description of the feverish idleness of Rick has the new note of one for whom a well meaning young man is no longer merely a "first walking gentleman." After a still more severe phase in *Hard Times* (1854) (historically important as the revolt of a Radical against the economic individualism which was originally identified with Radicalism) he continued the same tendency in *Little Dorrit* (1857), the tone of which is perhaps as sad as anything illustrated by Dickensian humours can be, broke off into an equally serious and more sensational experiment in historical romance in *A Tale of Two Cities* (1859), largely an effect of the influence of Carlyle, and finally reached what was perhaps the height of his new artistic method in a purely artistic sense. He never wrote anything better, considered as literature, than the first chapters of *Great Expectations* (1861). But there is, after all, something about Dickens that prevents the critic from being ever quite content with criticizing his work as literature. Something larger seems involved, which is not literature, but life, and yet the very opposite of a mere recorded way of living. And he who remembers Pickwick and Pecksniff, creatures like Puck or Pan, may sometimes wonder whether the work had not most life when it was least lifelike.

The stretch of stories following on *David Copperfield*, from 1850 onwards, fall into the framework of another of Dickens's editorial schemes, and this time a much more successful one. He began to edit *Household Words*, in which some, though not all of his later tales appeared, and continued to do so until he exchanged it in 1859 for another and similar periodical called *All the Year Round*. Just as we find him about this time induced at last to settle down finally in a comparatively comfortable editorial chair, so we find him at last settled more comfortably in a domicile that could really be called a home, when, returning at last to his beloved Rochester district on the great road of Kent, he set up his house at Gads hill. It is sad to realize that this material domestic settlement had followed on a moral unsettlement, and the separation of Dickens and his wife, by agreement (of which the little that needs saying has already been said) had already taken place in 1836. But indeed, even apart from that tragedy, it is typical of Dickens that his repose could never be taken as final. His life was destined to end in a whirlwind of an entirely new type of activity, which none the less never interrupted that creative work which was the indwelling excitement of all his days. He wrote one more complete novel, *Our Mutual*

Friend (1864-65), and it is more complete than most. Indeed it is one of the best though not one of the most Dickensian of the Dickens novels. He then turned his restless talent to something in the nature of a detective story, more in the manner of his friend Wilkie Collins, the sort of story which begins by asking a question, in this case a question about the secret and the sequel of the fate of the hero, Edwin Drood. The question will never be answered, for it was cut short by the only thing that could be more dramatic than the death of the hero, the death of the author. Charles Dickens was dead.

He died very suddenly, dropping from his chair at the dinner table, in the year 1870 at the comparatively early age of fifty-eight. A death so abrupt, and essentially so premature, could not but raise doubts about the wisdom of his impetuous industry and debates almost as varied as those round the secret of Edwin Drood. But without exaggerating any one of the elements that contributed to it, we may note that the very last phase of his life was a new phase, and was almost entirely filled with his new activity in giving public readings from his works. He had gone to America once more in the November of 1867, with this particular purpose, and his campaign of public speaking in this style was truly American in its scope and scale. If he had indeed been unjust to America as a writer, it is curious that he should have reached his final popularity and perhaps his final collapse, in a character so supremely American. Differences exist about how far he exaggerated the function or how far his biographer exaggerated the danger, but his own letters, ragged with insomnia and impatience, full of desperate fatigue and more desperate courage, are alone enough to show that he was playing a very dangerous game for a man approaching sixty. But it is certainly true, as is alleged on the other side, that this was nothing new in the general conduct of Dickens, that he had long ago begun burning the candle at both ends, and there have been few men, in the matter of natural endowments, with so great and glorious a candle to burn.

He was buried in the Poet's Corner of Westminster Abbey, and new and vulgar as many critics had called his work, he was far more of a poet than many who were buried there as poets. He left a will commending his soul to God, and to the mercy of Jesus Christ, and leaving his works to the judgment of posterity, and in both respects the action was symbolic and will remain significant in history. Intellectually limited as he was by the rather cheap and cherty negations of an age of commercial rationalism, he had never been a bitter secularist or anti-clerical, he was at heart traditional and was drawn much more towards Anglican than Puritan Christianity, and his greatest work may yet prove to be the perpetuation of the joyful mystery of Christmas. On the other side, he has suffered and may suffer again the thrills in the mere fashions of criticism, but his work was creative, it added something to life, and it is hard to believe that something so added will ever be entirely taken away. The defects of his work are glaring, they hardly need to be detected, they need the less to be emphasized because, unfortunately, he always emphasized them himself. It may be a fault, it is certainly a fact, that he enjoyed writing his worst work as much as his best.

The charge of exaggeration is itself exaggerated. It is also, which is much more important, merely repeated mechanically, without any consideration of its true meaning. Dickens did exaggerate, but his exaggeration was purely Dickensian. In this sense his very vulgarity had the quality of distinction. Mere overstatement, to say that a tall man is ten feet high, to say that a frosty morning froze Niagara, this is something relatively easy to do, though sometimes very cleverly done, especially by Americans. But the distinction of Dickens can be stated even in the common charge against him. He is said to have turned men into monsters of humour or horror, whereas the men were really commonplace and conventional persons in shops and offices. If any critic depreciates the Dickensian method as mere overstatement, the answer is obvious, let him take some of these commonplace people and overstate them. He will soon discover that he has not the vaguest notion of what to overstate. He will soon realise that it is not a simple matter of mere exaggeration, in the sense of

mere extension. It is not a matter of making a man a little taller or a morning a little colder, the challenge to imagination is not whether he can exaggerate, but whether he can find anything worth exaggerating. Now the genius of Dickens consisted in seeing in somebody, whom others might call merely prosaic, the germ of a sort of prose poem. There was in this or that man's attitude, or affection, or habit of thought, something which only needed a touch of exaggeration to be a charming fantasy or a dramatic contradiction. The books of Dickens are in fact full of bores, of bores who do not bore us, merely because they did not bore him. We have all of us heard a hundred times the tiresome trick of public speakers of asking themselves rhetorical questions which they do not want answered. Any of us might have heard a fit Dissenting minister doing it at a tea party and thankfully for gotten all about him. But Dickens seized on the fallacy and turned it into a fantasy, into Mr. Childbride's demands to know why he could not fly, or his wild and beautiful apologue about the elephant and the eel. We tell of the power of drawing people out, and that is the nearest parallel to the power of Dickens. He drew reeds and reeds of highly coloured caricature out of an ordinary person, as dazzlingly as a conjurer draws reeds and reeds of highly coloured pipes out of an ordinary hat. But if anybody thinks the conjuring trick is easy to perform, let him try it with the next ordinary person he sees. The exaggeration is always the logical extension of something that really exists, but genius appears, first in seeing that it exists, and second in seeing that it will bear to be thus exaggerated. That is something totally different from giving a man a long nose, it is the delicate surgical separation or extension of a living nerve. It is carrying a ludicrous train of thought further than the actual thinker carries it, but it requires a little thinking. It is making fools more gloriously foolish than they can be in this vale of tears, and it is not every fool who can do it.

There were other reasons for the injustice in the particular case of Dickens. Though his characters often were caricatures, they were not such wild caricatures as was supposed by those who had never met such characters. And the critics had never met the characters, because the critics did not live in the common life of the English people, and Dickens did. England was a much more amusing and horrible place than it appeared to the sort of man who wrote reviews in *The Quarterly*, and, in spite of all scientific progress or social reform, it is still. The poverty and anarchy of Dickens's early life had stuffed his memory with strange things and people never to be discovered in Tennyson's country houses or even Thackeray's drawing-rooms. Poverty makes strange bedfellows, the same sort of bedfellows whom Mr. Pickwick fought for the recovery of his nightcap. In the vivid phrase, he did indeed live in Queer street and was acquainted with very queer fish. And it is something of an irony that his tragedy was the justification of his farce. He not only learnt in suffering what he taught in song, but what he rendered, so to speak, in a comic song.

It is also true, however, that he caught many of those queer fish because he liked fishing in such troubled waters. A good example of this combination of opportunity and eccentricity is to be found in his affection for travelling showmen and vagabond entertainments of all sorts, especially those that exhibited giants and dwarfs and such monstrosities. Some might see in this truth a sort of travesty of all his travesties. It would be easy to suggest a psychological theory, by which all his art tended to the antics of the abnormal, it would also be entirely false. It would be much truer to say that Dickens created so many wild and fantastic caricatures because he was himself commonplace. He never identifies himself with anything abnormal, in the more modern manner. In his travelling show, the Giant always falls far short of being a Superman. And though he was tempted only too easily to an obvious pathos, there was never anything particularly pathetic about his dwarfs. His fun is more robust, and even, in that sense, more callous. The truth is that Dickens's attitude to the abnormal has been misunderstood owing to the modern misunderstanding of the idea of the normal. He was in many ways a wild satirist, but still a satirist, and satire is founded on sanity. He had his real

Cockney imitations. But his moderation was not a limitation but a liberty, for it allowed him to hit out in all directions. It was precisely because he had an ordinary and sensible view of life that he could measure the full madness both of Gradgrind's greed or Micawber's improvidence. It was because he was what we call commonplace that Dombey appeared to him so stiff or Jellyby so slovenly. In a later generation a real person often assumed such an unreal pose and lost the power of merely laughing at it, as, for example, when Oscar Wilde said seriously all that Skimpole had said absurdly. The Victorian commonsense was not a complete commonsense, and Dickens did suffer from having a narrower culture than Swift or Rabelais. But he did not suffer from being sensible, it was even more from his sense than his sensibility, it was from a sort of inspired irritation and impatience of good sense, that he was able to give us so radiant a fairyland of fools.

His literary work produced of course much more than a literary effect. He was the last great poet, in the true sense of maker, who made something for the people and was in the highest sense popular. He still gives his name, not to a literary clique, but to a league or fellowship numbering thousands all over the world. In this connection it is often noted that he achieved many things even considered as a practical political and social reformer. He led light into dark corners, like the dens of dirt and brutality often called schools, especially in Yorkshire, he probably had much to do with making the professional nurse a duller but more reliable person than Mrs. Gamp, it is likely enough that his vivid descriptions, assisted by the whole trend of the time, hastened the extinction of ordinary imprisonment for debt and clarified much of the original chaos of Chancery. But precisely because this has often been said, it will be well not to say it too often. It has the effect of making his satire appear much more superficial and utilitarian than it really was, for the great satirist is concerned with things not so easily destroyed. We do more honour to Dickens in noting the evils he did not destroy than those he did. The eager worship of a man merely wealthy, however dull and trivial, which appears in the affair of Merdle, has by no means disappeared from our own more recent affairs. The pompous old Barnacle and the agreeable young Barnacle are still almost as much alive as in Dickens's day. The sweeping away of a genuine gentry, in the person of Mr. Twemlow, on the tide of a new plutocracy, represented by Mr. Veneering, has gone much further than in Dickens's day. But this makes Dickens's satire the more rather than the less valuable to posterity. The other mood, which pictures all such abuses as things of the past, tends not to reform but only too much to repose, and to the perpetuation of a rather snobbish and paltry version of the Dickensian tradition. In that spirit we may hear to this day a Stiltskalking telling the House of Commons that Stiltsalkings have perished before the march of progress, or in the law courts a Buzfuz quoting Buzfuz and jeering at himself as an extinct monster.

The future of the work of Dickens is no part of the Dickens record and a ridiculous part of the Dickens criticism. Some have suggested that his glory will be in new editions, such as those he has tried, others have said, and just equally reasonably, that the distance it will take when all the editions have grown old, and that Americans and Americans have outlived their descendants as well as their contemporaries. But there can be no question of the importance of Dickens as a permanent in history, a sort of configuration and clarification in the very heart of what is called the civilization of Victorian era, a naked flame of mere natural genius, breaking out in a man without culture, without tradition, without help from historic religious or philosophies or from the great foreign schools, and revealing a light that it never was so at hand it only in the long fantastic shadows that it threw from common things.

DICKINSON, EMILY (1830-1886), American poet, was born on Dec. 10, 1830, at Amherst, Mass., where her grandfather, Samuel Fowler Dickinson, had been one of the founders of the town, church and college. Her father, Edward Dickinson, was a lawyer and treasurer of the college, her mother, Emily Norcross Dickinson, a model New England housewife who "did not care for thought." In all her heredity, according to her biographer, traced back nine generations in America and 13 in England, there is nothing to explain her genius—nor to confute it. As a child she went to public school, went berrying and chestnutting, learned the household arts and crafts. As a girl she made a herbarium, embroidered the usual book marks, and wrote sentimental letters in the verbose style of the time. In the fall of 1847 she entered South Hadley seminary, where she studied chemistry, physiology and English composition, and where she was "cramped, curbed and repressed in every natural desire or impulse." She left the seminary in 1848, re-entered Amherst academy for a while, and then, except for the lectures of the resident and visiting professors and her own reading, her education was finished. The winter of 1853 she spent in Washington, where her father was serving two terms in Congress, and on a visit to Philadelphia in the spring experienced an unhappy love affair—she firmly renouncing the man because she would not "wreck another woman's life." This possibly influenced the change from an apparently normal, witty young woman, to an increasingly mystical poet. By 1862 she had practically withdrawn from the world, venturing out of her father's house only at dusk to attend to her plants, but remaining always the "ecstatic darddevil, shy paradox," to her brother's family and to a very few intellectual friends. She died at Amherst on May 16, 1886. During her lifetime she had allowed only three or four of her poems to be published. In 1892 her friend, Col. Thomas Wentworth Higginson, published a small collection with a success almost unparalleled in American literature, but it was not until 1924 that her complete poems and her *Letters* were published, making her work generally accessible. Her poetry has been described as suggestive of William Blake in its "flashes of wholly original and profound insight into nature and life." She herself has been described as the epigrammatical Walt Whitman, and she remains a strange and entirely original genius, "defiant of outward form, sometimes obscure, at times inscrutable," but more often with a perfection in the mating of word and idea that has rarely been achieved.

DICKINSON, JOHN (1732-1808), American statesman and pamphleteer, was born in Talbot county, (Md.) Nov. 8, 1732. He removed with his father to Kent county (Del.), in 1740, studied under private tutors, read law, and, in 1753, entered the Middle Temple, London. Returning to America in 1757, he practised law in Philadelphia and started, in 1760, his long public career. Since Pennsylvania and Delaware were under the same proprietor and the same governor, he acted in the same capacity at various times for both colonies—member of the assembly, president of the executive council, and representative in the Continental Congress. He was sent from Pennsylvania to the Stamp Act Congress (1765), served for a time as private, and later as brigadier general, in the Delaware militia, and represented Delaware at the Annapolis Convention of 1786 and the Federal Constitutional Convention of 1787. He was most important, however, as the "Penman of the Revolution." Scarcely any other writer of the day presented arguments so numerous, so timely and so popular. He drafted the "Declaration of Rights" of the Stamp Act Congress, the "Petition to the King" and the "Address to the Inhabitants of Quebec" of the Congress of 1774, the second "Petition to the King" and "Articles of Confederation" of the Second Congress. Most influential of all, however,

were *Letters From a Farmer in Pennsylvania* written in 1767-68 in condemnation of the Townshend acts of 1767, in which he rejected speculative natural rights theories and appealed to the common sense of the people through simple legal arguments. By opposing the Declaration of Independence he lost his popularity and never entirely regained it. As the representative of a small state, he championed the principle of state equality in the Constitutional Convention, but he was one of the first to advocate the compromise, which was finally adopted providing for equal representation in one house and proportional representation in the other.

After the adjournment of the convention he defended its work in a series of forceful letters signed "Tribus". Largely through his influence Delaware and Pennsylvania were the first two states to ratify the constitution. Dickinson's interests were not exclusively political. He helped to found Dickinson college (named in his honour) at Carlisle Pa. in 1783 was the first president of its board of trustees and was for many years its benefactor.

He died Feb. 14, 1808, and was buried in the Friends' burial ground in Wilmington, Del.

See C. J. Stille, "Life and Times of John Dickinson," *Memoirs of the Historical Society of Pennsylvania*, vol. xiii (Philadelphia, 1901), P. L. Ford (ed.), "The Writings of John Dickinson," *Ibid.*, vol. xiv (1895), R. R. Richards, "The Life and Character of John Dickinson," *Delaware Historical Society Papers*, no. 10.

DICKINSON, WILLOUGHBY HYETT DICKINSON, 1ST BARON (1859-1945), British politician, was born April 9, 1859, the son of a British parliamentarian.

He attended Eton and Trinity college, Cambridge university, studied law and was called to the bar in 1884. He served on the London county council from 1889 to 1907 and served as its chairman in 1899.

He was chairman of the London Liberal federation, 1896-1918, and was made a privy councillor in 1914. He was created 1st Baron Dickinson of Painswick in 1930 and joined the Labour party in the same year.

Lord Dickinson, who was chairman of the League of Nations society, 1915-18, was one of the originators of the League of Nations. In 1923 he was substitute delegate to the Geneva assembly. He was also life president of the World Alliance for Promoting International Friendship Through the Churches.

He died at Painswick, Eng. on June 1, 1943.

DICKINSON, a city in the southwestern part of North Dakota, U.S., on the Heart river and federal highway 10, at an altitude of 2,430 ft., the county seat of Stark county. It is a division point on the Northern Pacific railway, which has repair shops there.

The population by the 1950 federal census was 7,469. Dickinson is the shipping point for a farming and grazing region, and has large livestock sales rings, lignite coal mines, a plant for the manufacture of briquets and a concrete block plant. One of the state teachers' colleges is located there, and the state agricultural college established a branch of the agricultural experiment station in Dickinson.

A bureau of reclamation dam, a portion of the Missouri basin project, spans the Heart river 1 mi. W. of the city. The city was settled about 1882 and incorporated in 1900.

DICKSEE, SIR FRANCIS BERNARD (1853-1928), English painter, born in London on Nov. 27, 1853, son of Thomas Dicksee, artist, was president of the Royal academy in 1924. He belongs to the older academic school, whose aim was to express poetic sentiments in a realistic pictorial form. His pictures are painted with extreme sensibility and his execution is always skilful and competent.

Two of his principal works were bought under the Chantrey bequest for the Tate gallery "Harmony" (1877) and "The Two Crowns" (1900).

He died Oct. 17, 1928.

DICKSON, SIR ALEXANDER (1777-1840), British artillery officer, attended the Royal Military academy. He entered the royal artillery in 1794.

Dickson served in Minorca (1798), at Malta (1800), in the Montevideo expedition (1806-07) and in 1809 accompanied Ho-

worth to the peninsula as brigade major of the artillery. In the end he became commander of the whole of the artillery of the allied army and though still only a substantive captain in the British service he had under his orders about 8,000 men. At Vittoria, the battle of the Pyrenees and Toulouse he directed the movements of the artillery. He served on the artillery staff at Quatre Bras and Waterloo, and subsequently commanded the British battering train at the sieges of the French fortresses left behind the advancing allies.

He died a major general and G.C.B. in 1840. He was an early fellow of the Royal Geographical society.

His diaries kept in the peninsula were the main source of information used in Duncan's *History of the Royal Artillery*.

DICKSON, SIR JAMES ROBERT (1832-1907), Australian statesman, was born in Plymouth, Eng., on Nov. 30, 1832. In 1854 he emigrated to Victoria but after several years spent in that colony and in New South Wales, he settled in 1862 in Queensland where he was connected with the Royal Bank of Queensland. He entered the Queensland house of assembly in 1872, and became minister of works (1876), treasurer (1876-79 and 1883-87), acting premier (1884), but resigned in 1887 on the question of taxing land.

In 1889 he retired from business and spent three years in Europe before resuming political life. He fought for the introduction of Polytechnic labour on the Queensland sugar plantations, at the general election of 1892 and was elected to the house of assembly in that year and again at the elections of 1893 and 1896. He became secretary for railways in 1897, minister for home affairs in 1898, represented Queensland in the federal council of Australia in 1896 and at the postal conference at Hobart in 1898, and in 1898 became premier. His energies were now devoted to the formation of an Australian commonwealth. He secured the reference of the question to a plebiscite, the result of which justified his anticipations.

He resigned the premiership in Nov. 1899, but in the ministry of Robert Philp, formed in the next month, he was reappointed to the offices of chief secretary and vice president of the executive council which he had combined with the office of premier. He represented Queensland in 1900 at the conference held in London to consider the question of Australian unity, and on his return was appointed minister of defense in the first government of the Australian commonwealth.

He died at Sydney on Jan. 10, 1907, in the midst of the festivities attending the inauguration of the new state.

DICKSON CITY, a borough of Lackawanna county, Pa., U.S.A., in the anthracite region. It is on the Lackawanna river, 5 mi. N.E. of Scranton, and is served by the Delaware and Hudson, the Erie, and the New York, Ontario and Western railways. The population in 1950 was 8,948 and in 1940, 11,545.

DICOTYLEDONS, in botany, the larger of the two great classes of angiosperms (*q.v.*), embracing most of the common flower-bearing plants. The name expresses the most universal character of the class, the importance of which was first noticed by John Ray, namely, the presence of a pair of seed leaves or cotyledons in the plantlet or embryo contained in the seed. The embryo is generally surrounded by a larger or smaller amount of foodstuff (known as the endosperm) which serves to nourish it in its development to form a seedling when the seed germinates; frequently, however, the whole of the nourishment for future use is stored in the cotyledons themselves, which in that case become thick and fleshy.

In germination of the seed the rudimentary root at the distal end of the hypocotyl develops the primary root, this is usually followed by growth of the hypocotyl which carries the cotyledons above ground, where they become the first green leaves of the plant. Lying between the bases of the cotyledons and terminating the axis of the plant is the first stem bud (epicotyl of the embryo).

Size and manner of growth of the adult plant show variety, from the small herb living for one season only to the forest tree living for centuries. The arrangement of the conducting tissue in the stem is characteristic, a transverse section of the very young stem shows a number of distinct conducting strands—vascular

bundles—arranged in a ring round the pith, these soon become united to form a closed ring of phloem and wood separated by a layer of cambium. In perennials the stem shows a regular increase in thickness each year by the addition of a new ring of wood outside the old one—for details of structure see PLANTS AND PLANT SCIENCE. *Anatomy of Plants*

A similar growth occurs in the root. This increase in the diameter of stem and root is correlated with the increase in leaf area each season, caused by the continued production of new leaf-bearing branches. A characteristic of the class is afforded by the complicated network formed by the leaf veins—well seen in a skeleton leaf from which the soft parts have been removed by maceration. The parts of the flower are most frequently arranged in fives or multiples of fives, for instance, a common arrangement is as follows—five sepals, succeeded by five petals, ten stamens in two sets of five, and five or fewer carpels. An arrangement in fours is less frequent, while the arrangement in threes so common in monocotyledons is rare in dicotyledons. In some families the parts are numerous, chiefly in the case of the stamens and the carpels as in the buttercup and other members of the Ranunculaceae and in the Rosaceae.

The characters of the flower and fruit are described in the articles FLOWER, FRUIT, and SEED.

DICTATING MACHINES see OFFICE MACHINES AND APPLIANCES

DICTATOR, in modern usage, a ruler enjoying extraconstitutional power, in ancient times, an extraordinary magistrate in the Roman commonwealth (from the Lat. *dictare*, frequentative of *dicere*). The earlier official title was *magister populi*, which may mean "head of the host" as opposed to his subordinate, the *magister equitum*, who was "head of the cavalry." Emphasis was thus laid on the military aspect of the dictatorship and in fact, the office seems to have been instituted for the purpose of meeting a military crisis too serious for the annual consuls with their divided command. The repression of civil discord was one of the motives for the institution of a dictatorship. This function of the office is attested by the internal history of Rome. In the crisis of the agitation at the time of the Licinian laws (367 B.C.) a dictator was appointed, and in 314 B.C. a dictator was created for purposes of criminal jurisdiction (*quaestioibus exercendis*). The dictator appointed to meet the dangers of war, sedition or crime was described as the "administrative dictator" (*rei gerundae causa*). He held office for six months.

The powers of a dictator were a temporary revival of those of the kings, with some limitations. The dictator was never concerned with civil jurisdiction. His military authority was confined to Italy, and his power of life and death was limited. By the *lex Valeria* of 300 B.C. he was made subject to the right of criminal appeal (*provocatio*) within the limits of the city. But all the magistrates of the people were regarded as his subordinates. The dictator was nominated by one of the consuls. But the senate claimed authority over the magistrates, and suggested not only the nomination but also the name of the nominee. After nomination, the *lex curata* confirmed the dictator's imperium (see COMITIA).

The first dictator is said to have been created in 501 B.C., the last of the "administrative" dictators belongs to the year 216 B.C. The epoch of the Second Punic War was marked by experiments with the office, such as the election of Q. Fabius Maximus by the people, and the co-dictatorship of M. Minucius. The emergency office of the early and middle republic has little in common with the dictatorship as revised by Sulla and by Caesar. Ostensibly to prevent its further abuse, M. Antonius in 44 B.C. carried a law abolishing the dictatorship.

Modern dictators, like the ancient ones, have taken over the reins of government in times of emergency, but they have used the powers thus gained to establish a permanent, autocratic and sometimes despotic rule. In this they resemble the ancient tyrants rather than the ancient dictators. Both Benito Mussolini and Adolf Hitler falsely posed as the defenders of popular rights, used democratic institutions and exploited the techniques of mass communication to cement their power. They became herds of the governments in their respective countries formally in accordance with

the existing constitutions, and even enjoyed some popular support in spite of their suppression of freedom. The Communist dictatorship in Russia was proclaimed originally as the temporary dictatorship of a political élite to preserve the Revolution, it became permanent and, under Joseph Stalin, was a personal one.

(Minneapolis, 1949).

DICTIONARY, a book listing words of a language, with their meanings in the same or another language, usually in alphabetical order, often with data regarding pronunciation, origin and usage.

The term "dictionary" in one of its Latin forms (*dictionarius*, a collection of words) was used c. 1225 by an English scholar, John Garland, as title for a manuscript of Latin words to be learned by heart. The words were arranged not in alphabetical order, but in groups according to subject. This *Dictionarius*, used only for the teacher's classroom work in teaching Latin, contained no English except for a few interlined glosses (translations of single words).

15th and 16th Centuries—In the 15th century English words did appear in dictionaries, but even then they were used only as an aid to the study of Latin, as in the famous *Promptorium Parvulorum* ("Storehouse for the Little Ones"), a pioneer English-Latin wordbook. This important manuscript, completed in Norfolk c. 1440, was the work of a Dominican friar known as Galfridus Grammaticus (Geoffrey the Grammarian). He listed about 12,000 English words mostly nouns and verbs, with their Latin equivalents, and for some time his dictionary held a place of leadership. The *Promptorium* was written several years before the invention of printing, but in 1499 it was published, at the London press of Richard Pynson, an early servant and associate of William Caxton.

The custom of giving colourful titles to dictionaries was followed for many years. In the *Promptorium* we had a "storehouse," and later, in 1500, came a "garden of words," for that is the meaning of *Ortus Vocabulorum*, printed by one of Caxton's assistants, Wynkyn de Worde. *Ortus*, a Low-Latin form of *hortus* (garden), shows that even scholars sometimes omitted the aspirate. In the *Ortus*, Latin words come first, translated by English. The book, like earlier ones, was designed for students of Latin.

What has been called the first real English dictionary, printed in 1552, was the *Abecedarium Anglicano-Latinum pro Tyrnuculis*, compiled by Richard Huloet. Huloet, sometimes addressed as "Maister Howlet," was a native of Wisbeach in Cambridgeshire. *Pro tyrnuculis* means "for young beginners," but Huloet seems to have intended his book for beginners of all ages, including adults whose main interest was to learn to read English. Latin study, as usual, was probably the goal of this work, but the Latin translation was not given until the English word had been defined in English, hence the *Abecedarium* can be regarded as an English dictionary. Huloet's style was informal and sometimes humorous, as may be judged from some of his definitions:

Bachler, or one unmarried, or having no wife, *Agamus, nris*
Black (or blew) spotted in the face or bodye, made with a stroke, as when a wife hath a blewie eye, she sayth she hath stombled on hir good man his lyfte. *Singulatio omis, Lovor, uaris*
Tymme wenche gorgeously decked, *Phalerata foemina*

Huloet doubtless felt that the resplendent young lady needed no further definition in English, and it should be noted that *wench*, in 1552, was a very proper word, it meant simply a girl or young woman.

The *Abecedarium*, which contained 26,000 words, was popular, but it was expensive. This fact was recognized by a Yorkshire schoolmaster and physician named Peter Levinus, who decided to write a smaller work, then, he said, "the price beinge little, the poorer sorte may be able to have it." Comparing Huloet's big book with his own little one, Levinus wrote, "This is for greater students, and them that are richable to have it, this is for beginners and them that are pooreable to have no better." From that day to this, rich

able and poorish have needed dictionaries, and generations of publishers have tried to serve them all. Following the custom of using a picturesque title, Levins named his book, published in 1570, *Manipulus Vocabulorum* "a handful of words," the handful comprising about 9,000 entries. He also called it, "a dictionary of English and Latine wordes, set forth in such order as none heretofore hath bene necessary not only for scholars that want variety of words, but also for such as use to write in English metre." To help the poets, he arranged his words not according to their initial letters, but by the spelling of their final syllables, which resulted in a sort of rhyming dictionary, the first of its kind in English. The final syllables, however, brought together some strange bedfellows such as casket, suet, bell, chusal, midime, surname, and—most confusing—bough, chough, though, though, which even in 1570 were probably not more than "eve rhymus."

In 1573 John Baret published a dictionary which he called *In Alvarie*, or 'beehive'. In this work an English word is given in English definition, and the equivalent in Latin, followed usually by French. Baret, an ingenious and doubtless popular educator, tells us how the book was compiled: "About eightene years ago, having pupils at Cambridge studious of the Latine tongue," they "perceiving what great trouble it was to come running to mee for every word they missed I appointed them every day to write English before we Latin and likewise to gather a number of fine phrases out of Cicero, Terence, Caesar, Livie etc. and to set them under severall titles, for the more ready finding them againe at their neede." Baret encouraged his pupil assistants by calling them his busy bees, and "within a yeare or two they had gathered together a great volume," like "diligent Bees in gathering their wax and hony into their Hive." Here is a sample entry from the *Alvarie*:

A GOAST, an image in man's imagination, *Spectrum*, *tri*, *Cu*, *Phantasme*, *visum*. La semblence des choses que nostre pensee s'incorpore.

17th Century—The compilers of early dictionaries made no attempt to include all words. They were satisfied to explain or define the hard words of the language, and often so stated. This custom was illustrated in 1604 when Robert Cawdrey issued his dictionary, *A Table Alphabeticall, conteyning and teaching the true writing and understanding of hard usuall English wordes with the interpretation thereof by plaine English wordes, gathered for the benefit & helpe of Ladies, Gentlewomen, or any other unskilfull persons*. Cawdrey was another schoolmaster, and his explanations of about 2,500 words may have been based in part on his classroom experience. Much of his work, however, was taken without acknowledgment from earlier writers. It was an era of borrowing, adapting and downright plagiarism, often on a scale that by modern standards would seem outrageous. But almost every writer added something of value, and as dictionaries increased in number they tended to increase also in usefulness. Cawdrey, perhaps recalling the informal or complicated groupings of words in some earlier dictionaries, stressed the importance of the word "alphabetical" in his title. Apparently some "unskilfull persons" in his day (as in ours) had not taken the trouble to learn their ABC's. So, he said, "Thou must learne the Alphabet, to wit, the order of the Letters as they stand."

At long last, in 1623, a work was issued entitled simply *The English Dictionary*. The author, or compiler, was "H. C. Gent.," who turned out to be Henry Cockeram. Much of his material was borrowed from Cawdrey and others, but for the use of the intelligencia he added some weird Latinesque words, such as "*Com-motrix*, A maid that makes ready and unready her Mistres, *Glauco-tate*, To cry like a whelp, *Torvis*, Sownessness of countenance." An amusing definition of a more familiar word was "*Ovali*, a long round circle like an Egge, wherein pictures are sometimes drawne in." Always dramatic, Cockeram calls his preface a "Pronomition" or forewarning, perhaps having in mind the third section of his book, a fearsome "recitall" of "Gods and Goddesses, Giants and Devils, Burds and Beasts" and signs and wonders miscellaneous. Here we are told that the "*Hem*" is "a subtil Beast, counterfeiting the voice of a man. He is sometimes male and sometimes fe-

In 1656 a London lawyer named Thomas Blount published a dictionary entitled *Glossographia*, loosely translated as 'in expounding of strange words.' The author addresses himself to readers of all classes, including "the more knowing Women and less knowing Men." Blount did the best he could to provide etymologies, which was commendable, but some of his definitions were more amusing than accurate, as when he says "Tomboy, a girl or wench that leaps up and down like a boy, comes from the Saxon *tumbe*, to dince."

The *Glossographia* was followed in 1658 by *The New World of English Words*, collected and published by E. P. "E. P." was Edward Phillips, a writer of only moderate ability. His *New World* was a pretentious work largely copied from his predecessors notably from Blount. The word "collected" on his title page was hardly frank enough; the truth would have been better expressed by "appropriated."

In 1656 Llisha Coles, teacher of shorthand Latin and English, issued *An English Dictionary* with brief and generally adequate definitions and a small but interesting selection of cant and slang expressions. Coles was ingenious, in his address "To the Reader" he wrote:

I am no friend to vain and tedious Repetitions, therefore you will often meet with words, explain'd in their Dependence and Relation to one another, and the Sense completed by taking them together. As for example

Lupa a She wolf that nourished *Romulus* in the *Lupercal* a place near *Rome*, where they celebrated the *Lupercalia*, feasts in honour of *Pan*, performed by the *Luperci*, Priests of *Pan*.

Coles died in 1680, but his dictionary was often reprinted and survived him by many years.

18th Century—John Kersey, an open minded and progressive lexicographer, is credited with a good small wordbook, *New English Dictionary*, issued in 1702 "by J. K. Philobibit." He also edited and revised Phillips' *New World of Words*, enlarging it in 1706 and somewhat abridging the enlarged version in 1708. Kersey was a pioneer in introducing and defining words of everyday use, which his predecessors had not troubled to do.

In 1721 was issued the *Universal Etymological English Dictionary*, a comprehensive work "compiled and Methodically digested" by 'N. Bailey, Philologos." This was Nathaniel Bailey, an ingenious and enterprising London schoolteacher. His book contained more words "than any English Dictionary before extant." In 1730 Bailey followed with his great *Dictionaryum Britannicum*, a folio volume "containing not only the Words, and their Explications, but the Etymologies," and "Illustrated with near Five Hundred Cuts." This was enlarged in 1736. Bailey was more than a lexicographer, he was a philosopher, an entertainer and a humorist. When he came to an important word, he was seldom satisfied merely to define it, he used it as an excuse for a little lecture, for example "*Woman* the female of the human race. Women have two Qualities, a good and a bad. This is, they are either a blessing or a curse, according to the use we make of them," then about 30 more lines of amusing commentary. Bailey was one of the pioneers in indicating pronunciation, or at least marking the stressed syllables. Bailey's work was revised and reprinted for many years, and when Samuel Johnson was preparing his own dictionary, he kept by his side an interleaved copy of Bailey's *Dictionaryum*.

Johnson, a sort of lexicographical giant, undertook, with very little aid, a work which in modern times would be entrusted to a corps of editors, subeditors and departmental experts numbered in the hundreds. In France and in Italy learned academies had been established, to preserve the purity of the national languages. Academic concepts of purity involved a tendency to oppose change, in spite of the fact that change is essential to the life and growth of language. Johnson, with the approval of many of his contemporaries, was expected to be a one-man academy, to set forth the English tongue in all its glory and, if possible, to crystallize it in a classic form. He hoped to do it all within three years, it took him nearly eight—little enough for such a mighty task. That the task was mighty could be realized by anyone who saw the two folio

usage by Samuel Johnson. A M And when it was all done, Johnson admitted in his preface that no scholar "can embalm his language and secure it from corruption," and that "no dictionary of a living tongue can ever be perfect, since while it is hastening to publication, some words are budding and some falling away."

Johnson was a skilled definer. He had a way of perceiving the essential character and use of a word and of explaining it clearly. He pioneered in the illustration of definitions "by examples from the best writers," a work involving long and painstaking research. A few of Johnson's definitions became famous for reasons that had nothing to do with scholarship, as when he wrote "*Lexicographer*, a writer of dictionaries, a harmless drudge," and "*Envy*, a hateful evil levied upon commodities, and adjudged not by the common judges of property, but writhes hired by those to whom envy is paid." Johnson's services to the science and art of lexicography were substantial and of lasting value. They set a high standard for later workers to keep in mind.

In 1791 came the *Critical Pronouncing Dictionary and Expositor of the English Language*, by John Walker, a 59-year-old actor with a trained and perceptive ear and a lively interest in all types of English pronunciation. Walker's dictionary is of value even now because of the author's thorough treatment of pronunciation problems. Its influence was felt throughout Britain and America. More than 40 editions were published. Walker, who died in 1807, was regarded as an authority as late as 1837, when Isaac Pitman, himself a famed phonetician, published a system of shorthand "founded on Walker's Principles of English Pronunciation."

In 1794, three years after Walker's first edition, another enterprising Londoner, James Hindmarsh, carried lexicography into a hitherto unexplored field with *A New Dictionary of Correspondences, or the Spiritual significations of words in the Sacred Scriptures*. This work, based on the researches of Emanuel Swedenborg, gave meanings not of words but of scriptural persons, places and things, as *Peter*, faith, *Egypt*, science, *Water*, truth.

Signs of US Initiative—As the 18th century drew to its close, more than 20% of the world's English-speaking people were inhabitants of the United States. Pledged to a policy of universal education, they felt the need of an English dictionary designed specifically for use in their primary schools. In 1798 this need was recognized by a Connecticut schoolmaster, Samuel Johnson, Jr., who issued in New Haven, Conn., a little book entitled *A School Dictionary*. Although this work was admittedly "a collection from previous authors," it was well received; it was the first English dictionary compiled by an American. In 1800 it was followed by another small book, *A selected, pronouncing and accented Dictionary*, of about 10,000 words, published at Soufield, Conn. Samuel Johnson, Jr., shared its authorship with John Elliott, pastor of the church in East Guilford. This Elliott-Johnson work showed signs of Americanization; it included a few words peculiar to America (tomahawk, wampum, Cincinnati), or considered to have American meanings (Capitol, federal, freshest). It quoted endorsements from 19 educators, clergymen and others, including Noah Webster, then famed as author of a spelling book. The Connecticut pioneers indicated pronunciation, somewhat crudely, by diacritical marks and an occasional footnote.

Now, also in 1800, came *The Columbian Dictionary*, by another New Englander, Caleb Alexander of Massachusetts. In this work, containing about 32,000 entries, American usage was recognized by a few words (cent, dime, dollar, elector, Congress, Congressional, lengthy, minute-man, Presidential, Yank), and honor, favor, color, savor, troop, wo, were so spelled. Some alternatives were listed: calendar-kalendar, checker-checker, screen-skreen, sponge spunge. Pronunciation was shown by respelling. Whereas the Connecticut pioneers had given much of their space to "choice" or fairly hard terms, Caleb Alexander included also the simple words, providing a vocabulary that could reasonably be called complete.

A few weeks before Alexander's work was published, Noah Webster of New Haven Conn., announced that he was planning a series of dictionaries. The first was published in 1806 as *A Compendious Dictionary of the English Language*. It contained about

40,000 words, with brief definitions. Webster spent years in language study and research to prepare for his masterpiece, *An American Dictionary of the English Language*, published in 1828 in two quarto volumes and thereafter in many revised and improved editions. The 1828 edition, which contained about 70,000 entries, earned general acceptance as an authority, even in England. Some of Webster's definitions were faulty, but many of them were confirmed, years later, when language study had become a science.

Still another New Englander, Joseph Emerson Worcester, issued three reputable dictionaries (1830, 1846, 1860), designed to record and not to reform American usage. Worcester's works were in some quarters preferred to Webster's, but Webster, who he died 22 years earlier than his rival, "had the last word," for he is remembered as America's foremost pioneer lexicographer.

Compilers of British dictionaries in the 19th century availed themselves generously of American aid. Sometimes they acknowledged their indebtedness, notably so in the case of the monumental *New English Dictionary on Historical Principles*, later known as the *Oxford English Dictionary*. This great work, conceived 70 years before its completion in 1928, listed and defined all recorded English words from the 7th century to the 20th. It showed each word in all its traceable forms, with dated quotations and with etymologies determined in the light of modern scholarship. Every possible use of a word was considered, with the result that the little word set, for instance, was allotted more than 22 large pages of three columns each. Pronunciation was indicated by scientific respelling.

The project involved years of research by hundreds of volunteers on both sides of the Atlantic. Editor in Chief James A. H. Murray stated that most of the co-operation from "men of Academic standing" came from "Professors in American Universities" and their students. In 1860 supervision of the American workers was in the hands of the Hon. G. P. Marsh of Vermont, in 1870 it was taken over by Prof. Francis A. March of Massachusetts, famed for his 50 years at Lafayette College in Pennsylvania. Both gentlemen were noted philologists, both in the pioneer tradition New Englanders and both were eager to help their British confederates in building a monument to their common tongue.

Historically important is *The Century Dictionary*, an *Encyclopedic Lexicon of the English Language*, first issued in 1889-91 in six volumes and edited by William Dwight Whitney of Yale. This work, which started as an authorized expansion and Americanization of the English *Imperial Dictionary*, was rich in words, etymologies and literary examples.

Much used in the 20th century are large one- or two-volume editions of Webster's and the *New Standard Dictionary* (the latter first published 1893-95), also graduated abridgments of such works for college, school and home use. The *Britannica World Language Dictionary*, published first in 1954 with the *New Practical Standard Dictionary*, has a master list of English words with their equivalents in French, German, Italian, Spanish, Swedish and Yiddish. In addition to the word list proper, this work includes letters of the alphabet, cardinal numbers, days of the week, months of the year and common first names, also data on grammar and pronunciation; there is a separate index for each language. Presenting modern British usage is *Wyld's Universal Dictionary of the English Language* (1932 or later editions).

America's contributions to the vocabulary are found in *Dictionary of American English* (Chicago, Oxford, 1936-44, out of print, but available in some public libraries), also, notably, in *Dictionary of Americanisms* (Chicago, 1951), the latter includes about 50,000 words and expressions, a large percentage of which have earned acceptance as normal English.

Lexicography as a science owes much to the researches of Jakob Grimm, one of the world's master philologists, discoverer of Grimm's law, and his hardly less famous brother, Wilhelm Grimm. These eminent scholars, who did not think it beneath them to write the stories known as "Grimm's Fairy Tales," collaborated in launching a German dictionary on scientific principles, the great *Deutsches Wörterbuch*, started in 1852 and completed years later by their followers. In many ways the *Wörterbuch* served as an aid to workers in other languages.

Also of international repute and service in this field was Émile Littré, French dictionaryman, philosopher and physician, whose *Dictionnaire de la langue française* (1863-72, supplements later) is one of the monuments of lexicography. Littré's work, a one-man task for more than 30 years, is a fascinating blend of science and genius. It served as a treasury, on which many later compilers have drawn freely.

Pierre Larousse (1817-75), a distinguished French educator, published the *Grand dictionnaire universel* in 15 volumes, virtually an encyclopaedia, completed in 1876 just after his death. His successors have issued a series of dictionaries to meet varied popular needs, such as the *Nouveau Larousse illustré*, the *Larousse universel* and the *Petit Larousse*, all of them revised from time to time.

BIBLIOGRAPHY—Some of the best essays on the making of dictionaries are found in prefaces of the important modern works of the 19th and 20th centuries mentioned above. Sprinkled works of value are *A Survey of English Dictionaries* by Milford M. Matthews (1923) and *The English Dictionary From Caedmon to Johnson* by De Witt Staines and G. E. Noyes (Chapel Hill, N.C., 1946, Oxford, 1947). Because of their special interest and importance, two foreign language works one of them quite old, may be mentioned. They are *Comment j'ai fait mon dictionnaire* by Émile Littré (new ed. Paris, 1897) and *Introducción a la Lexicografía Moderna* by Julio Casares (Madrid, 1950).

DICTION DE OMNI ET NULLO This is the name of the alleged Aristotelian principle of deductive inference. There are various formulations of it. That given by Crackenhorpe is perhaps as near to Aristotle's meaning as any. *Quandqu affirmatur (sive negatur) universaliter de aliquo, idem affirmatur (sive negatur) etiam de omni de quo illud praedicatur*. The more usual and concise form is, *Quod de aliquo omni praedicatur, praedicatur etiam de qualibet eius parte*.—"What is predicated of any whole is predicated of any part of it." If "whole" be taken to mean "a kind" (or "class" in the sense of a "kind" or "type," see CLASS), then the *dictum* may be said to express the principle, that is, the form or spirit, of deductive inference. It is invariably treated as formulating the principle of syllogistic inference, but (this is not quite correct, as it does not apply to syllogisms composed of singular terms, and, on the other hand, it applies to the immediate inference of a particular or singular proposition from a general proposition as much as to deductive syllogisms).

See H. W. B. Joseph, *Introduction to Logic* (1916), A. Wolf, *Essentials of Logic* (1926).

DICTYONEMA A genus of important fossils composed of numerous branches radiating from a centre, found from Cambria to Devonian times in Europe and North America and belonging to the group known as Graptolites (*q. v.*)

Dictyonema is also the name of a genus of lichens (*q. v.*)

DICTYUS CRETENSIS, of Chossus in Crete, the supposed companion of Idomeneus during the Trojan War, and author of a diary of its events.

The ms of this work, written in Phoenician characters, was translated into Greek by the order of Nero. In the 4th century A.D. a certain Lucius Septimius brought out *Dictyus Cretensis Ephemeris belli Troiani*, which professed to be a Latin translation of the Greek version. Possibly the Latin Ephemeris was the work of Septimius himself. Its chief interest lies in the fact that (with Dares Phrygius's *De excidio Troiae*) it was the source from which the Homeric legends were introduced into the romantic literature of the middle ages.

BIBLIOGRAPHY—Best edition by F. Meister (1871), with short but useful introduction and index of Latinity, see also G. Kortum, *Dictyus und Dares* (1874), with concise bibliography, E. Collinieux, *Étude sur Dictyus de Crète et Dares de Phrygie* (1887), with bibliography, F. Colagrosso, "Ditté Cretese" in *Atti della Accademia di Archeologia* (Naples, 1897, vol. 18, pt. 2), N. E. Griffin, *Dares and Dictyus Introduction to the Study of the Medieval Versions of the Story of Troy* (1907).

DICUL (# 825), Irish monk, grammarian and geographer. His *De mensura orbis terrae*, finished in 825, contains the earliest notice of a European discovery of and settlement in Iceland and the most definite Western reference to the old fresh-water canal between the Nile and the Red sea, blocked up in 767. In 795

Irish hermits had visited Iceland, where they marvelled at the perpetual day of midsummer. Relics of their settlements were found by the permanent Scandinavians in colonists of Iceland in the 9th century. Of the old Egyptian fresh water canal Dicul learnt from one "brother Fideles," probably another Irish monk, who, on his way to Jerusalem, sailed along the "Nile" into the Red sea—passing on his way the "Barns of Joseph" or Pyramids of Giza, which are well described. Dicul's reading was wide, he quotes from, or refers to, 30 Greek and Latin writers, the patristic St. Isidore and Orosius, and his contemporary the Irish poet Sedulius, he professes to utilize the alleged surveys of the Roman world executed by order of Julius Caesar, Augustus and Theodosius (whether Theodosius the Great or Theodosius II is uncertain).

A short astronomical treatise written between A.D. 814 and 816 and dedicated to Louis le Debonnaire, the Frankish king in whose kingdom Dicul was teaching, has been edited by Mario Eposito in the *Proceedings of the Royal Irish Academy*, vol. xxvi s. C (1907). Editions of the *De Mensura* were made by C. A. Wulkenier (Paris, 1907), A. Letronne (Paris, 1814) and G. Parthey (Berlin, 1870, best as to text). See also C. R. Beazley, *Dawn of Modern Geography*, vol. 1 (1897).

DIDA, a bush population of the French Ivory Coast between the Bindima river and the Rio Frasco. Their language is related to Bile.

See Delafosse, *Vocabulaires comparatifs* (1904).

DIDACHE, THE, or *Teaching of the (twelve) Apostles*. This early Christian document is one of the most important discoveries of the second half of the 19th century. There are several references to it in Eusebius and elsewhere, and by applying to these the methods of comparative criticism a rough reconstruction of its contents had been obtained. But in 1875 Bryennios discovered it in the Patriarchal Library at Constantinople, in the ms which also contains I and II Clement.

The *Didachē*, as we now have it in the Greek, falls into two marked divisions: (a) a book of moral precepts, opening with the words, "There are two ways," (b) a manual of church ordinances, linked on to the foregoing by the words, "Having first said all these things, baptize," etc. Each of these must be considered separately before we approach the question of the locality and date of the whole book, in its present form.

The author of the complete work, as we now have it, has modified an earlier document entitled *The Two Ways*, which may have been a Jewish manual carried over into the use of the Christian Church. Near the beginning he has inserted a considerable section containing, among other matter, passages from the Sermon on the Mount, in which the language of St. Matthew's Gospel is blended with that of St. Luke's. He has also added at the close a few sentences, beginning, "If thou canst not bear (the whole yoke of the Lord), bear what thou canst!" (vi 2), a d among minor changes he has introduced, in dealing with confession, reference to "the church" (iv 14).

The second part of the *Teaching* might be called a church directory. It consists of precepts relating to church life, which are couched in the second person plural, whereas *The Two Ways* uses throughout the second person singular. It appears to be a composite work. (1) First (vi 1-11) is a short sacramental manual intended for the use of local elders or presbyters, though such are not named, for they were not yet a distinctive order or clergy. This section was probably added to *The Two Ways* before the addition of the remainder. It orders baptism in the three fold name, and adds directions as to the manner of baptism and preparation for it. Then follows the Lord's Prayer, almost exactly as in St. Matthew, with a brief doxology—"for Thine is the power and the glory for ever." This is to be said three times a day. Next come three eucharistic prayers, the language of which is clearly marked off from that of the rest of the book, and shows parallels with the dictum of St. John's Gospel. As in Ignatius and other early writers, the eucharist, a real meal (x 1) of a family character, is regarded as producing immortality (cf. "spiritual food and drink and eternal life"). None are to partake of it save those who have been "baptized in the name of the Lord" (an expression which is of interest in a document which prescribes the threefold

formula) The "prophets" are not to be confined to these forms, but may "give thanks as much as they will." This appears to show that a "prophet," if present, would naturally preside over the eucharist. (2) The next section (vi 3-xiii) deals with the ministry of spiritual gifts as exercised by "apostles," "prophets" and "teachers." An apostle is to be "received as the Lord," but he must follow the Gospel precepts, stay but one or two days, and take no money, but only bread enough for a day's journey. Here we have that wider use of the term "apostle" to which Lightfoot had already drawn attention. A prophet, on the contrary, may settle if he chooses and in that case he is to receive tithes and first-fruits, "for they are your high priests." If he be once approved as a true prophet, his words and acts are not to be criticized, for this is the sin that shall not be forgiven. (3) Next comes a section (xiv, xv) reflecting a somewhat later development concerning fixed services and ministry, the desire for a stated service, and the need of regular provision for it, is leading to a new order of things. The eucharist is to be celebrated every Lord's Day, and preceded by confession of sins "appoint there fore unto yourselves bishops and deacons, worthy of the Lord, men meek and uncovetous, and true and approved, for they also minister unto you the ministration of the prophets and teachers." This is an arrangement recommended by one who has tried it, and he reassures the old fashioned believer who clings to the less formal régime (and whose protest was voiced in the Montanist movement), that there will be no spiritual loss under the new system. The book closes (chap xvi) with exhortations to steadfastness in the last days, at the coming of the "world deceiver" or Antichrist, which will precede the coming of the Lord. This section is perhaps the actual utterance of a Christian prophet, and may be of earlier origin than the two preceding sections.

It will now be clear that indications of the locality and date of the present *Teaching* must be sought for only in the second part, and in the Christian interpolations in the first part. We have no ground for thinking that the second part ever existed independently as a separate book. The whole work was in the hands of the writer of the seventh book of the *Apostolic Constitutions* (qv), who embodies almost every sentence of it, interspersing it with passages of Scripture, and modifying the precepts of the second part to suit a later (4th century) stage of church development, this writer was also the interpolator of the Epistles of Ignatius, and belonged to the Syrian Church. The *Apostolic Church Order* has several passages closely parallel to *The Two Ways*, but the only parallel to the second part of the *Teaching* is in a quotation from one of the eucharistic prayers. The anti-Jewish tone of the second part suggests the neighbourhood of Jews, from whom the Christians were, to be sharply distinguished. Either Egypt or Syria would satisfy this condition, and in favour of Syria is the fact that the presbyterate there was to a late date regarded as a rank rather than an office. But all that we can safely say as to locality is that the community here represented seems to have been out of touch with the larger centres of Christian life.

This last consideration helps us in discussing the question of date. For such an isolated community may have preserved primitive customs for some time after they had generally disappeared. Certainly the stage of development is an early one, as is shown, e.g., by the prominence of prophets, and the need that was felt for the vindication of the position of the bishops and deacons (there is no mention at all of presbyters), moreover, there is no reference to a canon of Scripture (though the written Gospel is expressly mentioned) or to a creed. On the other hand the "apostles" of the second part are obviously not "the twelve apostles" of the title, and the prophets seem in some instances to have proved unworthy of their high position. The ministry of enthusiasm which they represent is about to give way to the ministry of office, a transition which is reflected in the New Testament in the 3rd Epistle of John. Three of the Gospels have clearly been for some time in circulation, St. Matthew's is used several times, and there are phrases which occur only in St. Luke's, while St. John's Gospel lies behind the eucharistic prayers which the writer has embodied in his work. There are no indications of any form of doctrinal heresy as needing rebuke, the warnings against false teaching are quite general. While the first part must be dated before the Epistle

of Barnabas, i.e., before A.D. 90, it seems wisest not to place the complete work much earlier than A.D. 120, and there are passages which may well be later.

BIBLIOGRAPHY.—A large literature has sprung up round *The Didache* since 1884. Harnack's edition in *Texte und Untersuchungen* vol. ii (1884) is indispensable to the student, and his discussions in *Geschichte der altchristlichen Literatur* give clear summaries of his work. Other editions of the text are those of F. X. Funk, *Fides Apostolica*, vol. i (Tübingen, 1901), H. Lietzmann (Bonn, 1903), with Latin version. Dr. C. Taylor in 1886 drew attention to some important parallels in Jewish literature, his edition contains an English translation. Dr. Rendell Harris published in 1887 a complete facsimile, and gathered a great store of patristic illustration. Text and translation will also be found in Lightfoot's *Apostolic Fathers* (shorter edition). The fullest critical treatment in English is by Dr. Vernon Bartlett in the extra volume of Hastings's *Dictionary of the Bible*, the most complete commentary on the text is by P. Drews in Hennecke's *Handbuch zu den N.F. Apocryphen* (1904). The most convenient edition with text and translation is that of Kirsopp Lake, *The Apostolic Fathers* vol. i (the Loeb Classical Library).

DIDACTIC POETRY, that form of verse the aim of which is less to excite the hearer by passion or move him by pathos than to instruct his mind and improve his morals. The Greek word *διδασκαλική* signifies apt for teaching, and poetry of the class under discussion approaches us with the arts and graces of a schoolmaster. Modern criticism is inclined to exclude the term 'didactic poetry' from our nomenclature, as a phrase absurd in itself and indeed obsolete. But in earlier times, in the absence of all written books, this was the easiest way in which information could be made attractive to the ear and be retained by the memory.

In the prehistoric dawn of Greek civilization there was a great body of verse occupied entirely with increasing the knowledge of citizens in useful branches of art and observation, these were the beginnings of didactic poetry, and we class them together under the dim name of Hesiod. *The Works and Days*, which passes as the direct masterpiece of Hesiod (qv), may be taken as the type of all the poetry which has had education as its aim. In somewhat later times, as the Greek nation became better supplied with intellectual appliances, the stream of didactic poetry flowed more and more closely in one, and that a theological, channel. The great poem of Parmenides, *On Nature* and those of Empedocles exist only in fragments, but enough remains to show that these poets carried on the didactic method in mythology. Cleostratus of Tenedos wrote an astronomical poem in the 6th century, and Pindar wrote a medical one in the 4th, but didactic poetry did not flourish again in Greece until the 3rd century, when Aratus, in the Alexandrian age, wrote his famous *Phenomena*, a poem about things seen in the heavens.

By far the greatest didactic Latin poem known to us is Lucretius, who composed, in the 1st century before Christ, his magnificent *De rerum natura*. By universal consent, this is the noblest didactic poem in the literature of the world. It was intended to instruct mankind in the interpretation and in the working of the system of philosophy revealed by Epicurus. What gave the poem of Lucretius its extraordinary interest, and what has prolonged and even increased its vitality, was the imaginative and illustrative insight of the author, piercing and lighting up the recesses of human experience. On a lower intellectual level, but of a still greater technical excellence, was the *Georgics* of Virgil, a poem on the processes of agriculture published about 30 B.C. The brilliant execution of this famous work has justly made it the type and unapproachable standard of all poetry which desires to impart useful information in the guise of exquisite literature. In the rest of surviving Latin didactic poetry the influence and the imitation of Virgil and Lucretius are manifest. Manilius produced a fine *Astronomica* towards the close of the reign of Augustus. Columella, regretting that Virgil had omitted to sing of gardens, composed a smooth poem on horticulture. Natural philosophy inspired Lucilius junior, of whom a didactic poem on *Etna* survives. Long afterwards, under Diocletian, a poet of Carthage, Nemesianus, wrote in the manner of Virgil the *Cynegética*, a poem on hunting with dogs, which has had numerous imitations in later European literatures.

In Anglo-Saxon and early English poetic literature, and espe-

cially in the religious part of it, an element of didacticism is not to be overlooked. The first English poem, however, which we can in any reasonable way compare with the classic works of which we have been speaking is the *Hundred Good Points of Husbandry* published in 1557 by Thomas Tusser, these humble Gospels aimed at a practical description of the whole art of English farming. In the early part of the 17th century one or two writers appeared who were as didactic as the age would permit them to be, Samuel Daniel with his philosophy, Iulius Greville (Lord Brooke) with his 'treatises' of war and monarchy. After the Restoration, as the lyrical element rapidly died out of English poetry, there was more and more room left for educational rhetoric in verse. The poems about prosody, founded upon Horace and signed by John Sheffield, 3rd earl of Mulgrave (1648-1721), and Lord Roscommon, were among the earliest purely didactic verse studies in English. John Philips deserves a certain pre-eminence, as his poem called *Cyder*, in 1700, set the fashion, which lasted all down the 18th century, of writing precisely in verse about definite branches of industry or employment. None of the greater poets of the age of Anne quite succumbed to the practice, but there is a very distinct flavour of the purely didactic about a great deal of the verse of Pope and Gray. In such productions as Gilbert West's (1703-56) *Education*, Dyer's *Fleece*, and Somerville's *Chase*, technical information is put forward as the central aim of the poet. In 1748 Gray began, though he failed to finish, a didactic poem on *The Alliance of Education and Government*. Didactic poems were discredited by the publication of *The Sugar Cane* (1704), a long verse-treatise about the cultivation of sugar by negroes in the West Indies, by James Grainger (1721-66). Whether so great a writer as Cowper is to be counted among the didactic poets is a question on which readers of *The Task* may be divided, this poem belongs rather to the class of descriptive poetry, but a strong didactic tendency is visible in parts of it. Perhaps the latest frankly educational poem which enjoyed a great popularity was *The Course of Time* by Robert Pollok (1798-1827), in which a system of Calvinistic divinity is laid down in the pomp of blank verse. This kind of literature had already been exposed, and discouraged, by the teaching of Wordsworth, who had insisted on the imperative necessity of charging all poetry with imagination and passion. Oddly enough, *The Excursion* of Wordsworth himself is perhaps the most didactic poem of the 19th century, but it must be acknowledged that his influence, in this direction, was saner than his practice.

The history of didactic poetry in France repeats, in great measure, but in drearier language, that of England. Boileau, like Pope, but with a more definite purpose as a teacher, offered instruction in his *Art poétique* and in his *Epistles*. But his doctrine was always literary, not purely didactical. At the beginning of the 18th century the younger Racine (1692-1763) wrote sermons in verse, and at the close of it the Abbé Delille (1738-1813) tried to imitate Virgil in poems about horticulture.

During the century which preceded the Romantic revival of poetry in Germany didactic verse was cultivated in that country on the lines of imitation of the French, but with a greater dryness and on a lower level of utility. Modern German literature began with Martin Opitz (1597-1639) and the Silesian School, who were in their essence rhetorical and educational, and who gave their tone to German verse. Albrecht von Hiller (1708-77) brought a very considerable intellectual force to bear on his huge poems, *The Origin of Evil*, which was theological, and *The Alps* (1729), botanical and topographical. Johann Peter Uz (1720-96) wrote a *Theodæce*, which was very popular, and not without dignity. Johann Jacob Dusch (1725-87) undertook to put *The Sciences* into the eight books of a great didactic poem. Tiedge (1752-1840) was the last of the school, in a once famous *Urania* he sang of God and Immortality and Liberty. These German pieces were the most unswervingly didactic that any modern European literature has produced. There was hardly the pretence of introducing into them descriptions of natural beauty, as the English poets did, or of grace and wit like the French.

DIDEROT, DENIS (1713-1784), French man of letters and encyclopaedist, was born at Langres on Oct. 5, 1713. He was

educated by the Jesuits, and then threw himself into the vagabond life of a bookseller's hack in Paris. An imprudent marriage (1741) did not better his position. His wife, Anne Tonnetie Champion, was a devout Catholic, but her piety did not restrain a narrow and fretful temper, and Diderot's domestic life was irregular and unhappy. He sought consolation, first with a Mridame Pussieux, and then with Sophie Volland, to whom he was constant for the rest of her life. His letters to her are among the most graphic of all the pictures that we have of the daily life of the *philosophes* who dined once a week at the baron D'Holbach's, to listen to the wild sallies and the inspiring declamations of Diderot.

Diderot earned a little by doing various translations, among these being one of Shaftesbury's *Inquiry Concerning Virtue and Merit* (1745), with some original notes of his own. He then composed a volume of stories, the *Biour misérables* (1748), of which he afterwards repented. From 1748 Diderot went back to the more congenial region of philosophy. Between the morning of Good Friday and the evening of Easter Monday he wrote the *Pensées philosophiques* (1746), and he presently added a short complementary essay on the sufficiency of a natural religion. In these he pressed the ordinary rationalistic objections to a super-natural revelation. In 1747 he wrote the *Promenade du sceptique*. Diderot's next piece was his famous *Lettre sur les aveugles* (1749). The immediate object of this short but pithy writing was to show the dependence of man's ideas on their five senses. It considers the case of the militant deprived of the aid of one of the senses, and in a second part, published afterwards, Diderot considered the case of a similar deprivation in the deaf and dumb. The *Lettre sur les sourds et muets*, however, is substantially a digressive examination of some points in aesthetics. The philosophic significance of the two essays is in the advance they make towards the principle of relativity. But what interested the militant philosophers of that day was an episodic application of the principle of relativity to the master conception of God. What makes the *Lettre sur les aveugles* interesting is its presentation, in a distinct though undigested form, of the modern theory of variability, and of survival by superior adaptation. It is worth noticing, too, as an illustration of the comprehensive freedom with which Diderot felt his way round any subject he approached, that in this theoretic essay he suggests the possibility of teaching the blind to read through the sense of touch. The speculation of the *Lettre sur les aveugles* was too hardy for the authorities, and he was thrown into the prison of Vincennes, where he spent three months, on his release he entered on the gigantic undertaking of his life.

A MONUMENTAL WORK

The Encyclopaedia.—The bookseller Lebreton had suggested to him the publication of a translation into French of Ephraim Chambers's *Cyclopaedia*, undertaken in the first instance by an Englishman, John Mills, and a German, Gottfried Sellius (for particulars see ENCYCLOPÆDIA). Diderot accepted the proposal, but in his busy and pregnant intelligence the scheme became transformed. He persuaded the bookseller to enter upon a new work, which should collect under one roof all the active writers, all the new ideas, all the new knowledge, that were then moving the cultivated class to its depths, but still were comparatively ineffectual by reason of their dispersion. His enthusiasm infected the publishers, D'Alembert was persuaded to become Diderot's colleague, the requisite permission was procured from the Government, and in 1751 the first volume was given to the world. The last of the letterpress was issued in 1765, but it was 1772 before the subscribers received the final volumes of the plates. These 20 years were to Diderot years not merely of incessant drudgery, but of harassing persecution, of sufferings from the cabals of enemies, and of injury from the desertion of friends. The ecclesiastical party detested the *Encyclopaedia*, in which they saw a rising stronghold for their philosophic enemies. By 1757 they could endure the sight no longer. To any one who turns over the pages of these redoubtable volumes now, it seems surprising that their doctrines should have stirred such portentous alarm. There is no atheism, no overt attack on any of the cardinal mysteries of the faith, no direct denunciation even of the notorious abuses of the

church. Yet the atmosphere of the book may well have been displeasing to authorities who had not yet learnt to encounter the modern spirit on equal terms. The *Encyclopædia* takes for granted the justice of religious tolerance and speculative freedom. It asserts in distinct tones the democratic doctrine that it is the common people in a nation whose lot ought to be the main concern of the nation's Government. From beginning to end it is one unbroken process of exaltation of scientific knowledge on the one hand, and pacific industry on the other. All these things were odious to the old governing classes of France, their spirit was absolutist, ecclesiastical and military. Perhaps the most alarming thought of all was the current belief that the *Encyclopædia* was the work of an organized band of conspirators against society, and that a pestilent doctrine was now made truly formidable by the confederation of its preachers into an open league. When the seventh volume appeared, it contained an article on "Geneva," written by D'Alembert. The writer contrived a panegyric on the pastors of Geneva, of which every word was a stinging reproach to the abbés and prelates of Versailles. At the same moment Helvétius's book, *L'Esprit*, appeared, and gave a still more profound shock to the ecclesiastical party. In 1759 the *Encyclopædia* was formally suppressed.

The decree, however, did not arrest the continuance of the work. It went on, but with its difficulties increased by the necessity of being clandestine. D'Alembert, wearied of shifts and indignities, withdrew from the enterprise. Other powerful colleagues, Turgot among them, declined to contribute further. Diderot was left to bring the task to an end as he best could. For seven years he laboured like a slave at the ear. He wrote several hundred articles, some of them very slight, but many of them most laborious, comprehensive and ample. He spent his days in the workshops, mastering the processes of manufactures, and his nights in reproducing on paper what he had learnt during the day. And he was incessantly harassed all the time by alarms of a descent from the police. At the last moment, when his immense work was just drawing to an end, he discovered that the bookseller had struck out from the proof sheets, after they had left Diderot's hands, all passages that he chose to think too hardy. The monument to which Diderot had given the labour of 20 long and oppressive years was irreparably mutilated and defaced. It is calculated that the average annual salary received by Diderot for his share in the *Encyclopædia* was about £120 sterling. "And then to think," said Voltaire, "that an army contractor makes £800 a day!"

Other Works.—Although the *Encyclopædia* was Diderot's monumental work, he is the author of a shower of dispersed pieces that sowed nearly every field of intellectual interest with new and fruitful ideas. He wrote plays—*Le Fils naturel* (1757), and *Le Père de famille* (1758), which he accompanied by essays on dramatic poetry, including especially the *Paradoxe sur le comédien*, in which he announced the principles of a new drama—the serious, domestic, bourgeois drama of real life, in opposition to the stilted conventions of the classic French stage. Diderot's lessons and example gave a decisive bias to the dramatic taste of Lessing, whose plays and *Hamburgische Dramaturgie* (1768) mark an epoch in dramatic history. Diderot's most intimate friend was Grimm, who wrote news letters to various high personages in Germany, reporting what was going on in the world of art and literature in Paris. Diderot helped his friend at one time and another between 1759 and 1779, by writing for him an account of the annual exhibitions of paintings. These *Salons* are among the most readable of all pieces of art criticism. They have a freshness, a reality, a life, which take their readers into a different world from the dry and conceited pedantries of the ordinary virtuoso.

DIDEROT'S VERSATILITY

Diderot's interest in human nature expressed itself in didactic and sympathetic form, in two, however, of the most remarkable of all his pieces, it is not sympathetic, but ironical. *Jacques le fataliste* (written in 1773, but not published until 1796) is in manner an imitation of *Tristram Shandy* and *The Sentimental Journey*. *Le Neveu de Rameau* is a far superior performance. Its intention has been matter of dispute, whether it was designed to be merely a satire on contemporary manners, or a reduction of the

theory of self interest to an absurdity, or the application of an ironical clincher to the ethics of ordinary convention, or a mere setting for a discussion about music, or a vigorous dramatic sketch of a parasite and a human original. There is no dispute as to its curious literary flavour, its mixed qualities of pungency, bitterness, pity and, in places, unflinching shamelessness. Goethe's translation (1805) was the first introduction of *Le Neveu de Rameau* to the European public. After executing it, he gave back the original French manuscript to Schiller, from whom he had it. No authentic French copy of it appeared until 1833.

It would take several pages merely to contain the list of Diderot's miscellaneous pieces, from an infinitely graceful title like the *Regrets sur ma vieille robe de chambre* up to *Le Reve de D'Alembert*, where he plunges into the depths of the controversy as to the ultimate constitution of matter and the meaning of life. It is a mistake to set down Diderot for a coherent and systematic materialist. We ought to look upon him "as a philosopher in whom all the contradictions of the time struggle with one another" (Rosenkranz). That is to say, he is critical and not dogmatic. There is no unity in Diderot, as there was in Voltaire or in Rousseau. Yet he drew at last to the conclusions of materialism, and contributed many of its most declamatory pages to the *Système de la nature* of his friend D'Holbach,—the very Bible of atheism, as some one styled it. All that he saw, if we reduce his opinions to formulae, was motion in space, "attraction and repulsion, the only truth." If matter produces life by spontaneous generation, and if man has no alternative but to obey the compulsion of nature, what remains for God to do? In proportion as these conclusions deepened in him, the more did Diderot turn for the hope of the race to virtue, in other words, to such a regulation of conduct and motive as shall make us tender, pitiful, simple, contented. Hence his one great literary passion, his enthusiasm for Richardson, the English novelist. Hence, also, his deepening aversion for the political system of France, which makes the realization of a natural and contented domestic life so hard. Diderot had almost as much to say against society as even Rousseau himself. The difference between them was that Rousseau was a fervent theist. The atheism of the Holbachians, as he called Diderot's group, was intolerable to him, and this feeling, aided by certain private perversities of humour, led to a breach of what had once been an intimate friendship between Rousseau and Diderot (1757). Diderot was still alive when Rousseau's *Confessions* appeared, and he was so exasperated by Rousseau's stories about Grimm, then and always Diderot's intimate, that in 1782 he transformed a life of Seneca, that he had written four years earlier, into an *Essai sur les règnes de Claude et de Néron* (1778–82), which is much less an account of Seneca than a vindication of Diderot and Grimm, and is one of the most rambling and inept productions in literature. As for the merits of the old quarrel between Rousseau and Diderot, we may agree with the latter, that too many sensible people would be in the wrong if Jean Jacques was in the right.

Diderot's mental activity was not of a kind to bring him riches. He could not even obtain that bare official recognition of merit which was implied by being chosen a member of the Academy. The time came for him to provide a dowry for his daughter, and he saw no other alternative than to sell his library. When the empress Catherine of Russia heard of his straits, she commissioned an agent in Paris to buy the library at a price equal to about £1,000 of English money, and then handsomely requested the philosopher to retain the books in Paris until she required them, and to constitute himself her librarian, with a yearly salary. In 1773 Diderot passed some months at St. Petersburg. The empress received him cordially. The strange pair passed their afternoons in disputes on a thousand points of high philosophy, and they debated with a vivacity and freedom not usual in courts. "Fy, donc," said Catherine one day, when Diderot hinted that he argued with her at a disadvantage, "is there any difference among men?" Diderot returned home in 1774. Ten years remained to him, and he spent them in the industrious acquisition of new knowledge, in the composition of a host of fragmentary pieces, and in luminous declamations with his friends. Diderot was seen at his best in conversation. "He who only knows Diderot in his writings," says

Marmontel, "does not know him at all. When he grew intimate in talk, and allowed his thoughts to flow in all their abundance, then he became truly ravishing. In his writings he had not the art of ensemble, the first operation which orders and places everything was too slow and too painful to him."

Diderot died on July 30, 1784, six years after Voltaire and Rousseau, one year after his old colleague D'Alembert, and five years before D'Holbach, his host and intimate for a lifetime. An elaborate and exhaustive collection of his writings in 20 stout volumes, edited by MM. Assézat and Tournoux, was completed in 1875-77 (J. Mo, X.).

In English Diderot has been the subject of a biography by John Morley (Viscount Morley of Blackburn) (1878). See also Karl Rosenkranz, *Diderots Leben und Werke* (1866). G. Hirn, *Diderot* (Stockholm, 1917). F. Hermand, *Les Idées morales de Diderot* (1923). For a discussion of the authenticity of the posthumous works of Diderot see R. Dominic in the *Revue des deux mondes* (Oct. 15, 1902).

DIDIUS SALVIUS IULIANUS, MARCUS, Roman emperor for two months (March 28-June 2, A.D. 193). He was the grandson of Salvius Iulianus, a famous jurist under Hadrian and the Antonines, and the son of a distinguished general. On the death of Pertinax, the pretorian guards offered the throne to the highest bidder. Didius and Sulpicianus (prefect of the city) bid against each other, and finally the throne was knocked down to Didius. The senate and nobles professed their loyalty, but the people made no attempt to conceal their indignation at this insult to the State, and the armies of Britain, Syria and Illyricum revolted. Septimius Severus, the commander of the Pannonian legions, was declared emperor and hastened to Italy. Didius, abandoned by the pretorians, was condemned and executed by order of the senate, which at once acknowledged Severus.

DIDO or **ELISSA**, the reputed founder of Carthage (q.v.), daughter of the Tyrian King Muttou, wife of Acerbas. Her husband having been slain by her brother Pygmalion, Dido fled to Cyprus, and thence to the coast of Africa, where she purchased from a local chieftain, Iarbas, a piece of land on which she built Carthage. The city soon began to prosper and Iarbas sought Dido's hand in marriage, threatening her with war in case of refusal. To escape from him, Dido constructed a funeral pile, on which she stabbed herself before the people (Justin VIII 4-7). Virgil, in defiance of the usually accepted chronology, makes Dido a contemporary of Aeneas, with whom she fell in love after his landing in Africa, and attributes her suicide to her abandonment by him at the command of Jupiter. Dido was identified with the Virgo Caelestis, i.e., Tanit, the tutelary goddess of Carthage. Timaeus is the oldest authority for the story, the meaning of the name Dido is uncertain.

DIDON, HENRI (1840-1900), French Dominican, was born at Trouvet, Isère, on March 17, 1840. Joining the Dominicans in 1858, he completed his theological studies at the Minerva convent at Rome. His brilliant preaching career began on his return to Paris in 1868. He concentrated on the relations between religion and science, and social problems, especially divorce. His disputes with the secular press led his superiors to interdict him from preaching and send him to the convent of Corbari in Corsica, whence he visited Palestine and also the German universities. In 1802 he returned to France, becoming director of the Collège Albert le Grand at Arcueil, and founding three auxiliary institutions, École Lacordaire, École Laplace and École St. Dominique. He wrote several works on educational questions, an often translated *Life of Christ* (Paris, 1890), and *Les Allemands* (Eng. trans. 1884). His *Spiritual Letters* have been translated by A. G. Nash (London, 1906). He died at Toulouse on March 11, 1900.

See the biographies by J. de Romano (1802) and A. de Coulanges (1900), and especially Stanislas Reynaud, *Le Père Didon: sa vie et son oeuvre* (1901).

DIDOT, the name of a family of famous French printers and publishers. FRANÇOIS DIDOT (1690-1757) founder of the greatness of his family, was born at Paris. He began business as a bookseller and printer in 1713, and among his famous productions was a collection of the travels of his friend the Abbé Prevost, in twenty volumes (1747). FRANÇOIS AMBROISE DIDOT (1730-1804), son of François, made important improvements in type founding, and was the first to attempt printing on vellum paper (1730). Among the works which he published was the famous collection of French classics prepared by order of Louis XVI for the education of the Dauphin, in *usum Delphini*, and the folio edition of *L'Art de vérifier les dates*. PIERRE FRANÇOIS DIDOT (1752-1795), his brother, devoted much attention to the art of type founding and to paper making. Among the works which issued from his press was an edition in folio of the *Imitatio Christi* (1788). HENRI DIDOT (1765-1852), son of Pierre François, is celebrated for his "microscopic" editions of various standard works, for which he engraved the type when nearly seven years of age. He was also the engraver of the *Assiégés* issued by the Constituent and Legislative Assemblies and the Convention. DIDOT SAINT-LÉGER (1767-1829), second son of Pierre François, was the inventor of the paper making machine known in England as the Didot machine. PIERRE DIDOT (1760-1853) eldest son of François Ambroise, is celebrated as the publisher of the beautiful "Louvain" editions of Virgil, Horace and Racine. The Raine in three volumes folio, was pronounced in 1801 to be "the most perfect typographical production of all ages." FIRMIN DIDOT (1764-1836), his brother, second son of François Ambroise, invented the process of stereotyping, and coined its name. He was the author of two tragedies—*La Reine de Portugal* (1824) and *La Mort d'Annibal* (1817), and he wrote metrical translations from Virgil, Thyraeus and Theocritus. AMBROISE FIRMIN DIDOT (1790-1876) was his eldest son. On the retirement of his father in 1827 he undertook, in conjunction with his brother HENRI DIDOT, the direction of the publishing business. Their greatest undertaking was a new edition of the *saecula Graecae linguae* of HENRI ESTIENNE, under the editorial care of the brothers Didot and M. Hase (9 vols., 1855-1859). Among the numerous important works published by the brothers, the 200 volumes forming the *Bibliothèque des auteurs grecs*, *Bibliothèque latine*, and *Bibliothèque française*, deserve special mention. Ambroise Firmin Didot was the first to propose (1823) a subscription in favour of the Greeks, then in insurrection against Turkish tyranny. The works include a translation of Thucydides. In 1875 he published a very learned and elaborate monograph on Aldus Manutius. His collection of mss., the richest in France, was said to have been worth, at the time of his death, not less than 2,000,000 francs.

See P. G. Brunet, *Firmin Didot et sa famille* (1870).

DIDYMI or **DIDYMA**, an ancient sanctuary of Apollo in Asia Minor in the territory of Miletus and on the promontory Poseideion. It was sometimes called *Branchidae* from the name of its priestly caste which claimed descent from Branchus, a youth beloved by Apollo. As the seat of a famous oracle, the original temple attracted offerings from Pharaoh Necho (in whose army there was a contingent of Milesian mercenaries), and the Lydian Croesus, and was plundered by Darius of Persia. Xerxes finally sacked and burnt it (481 B.C.) and exiled the Branchidae to the far north east of his empire. The celebrated cult statue of Apollo by Cnecachus, familiar to us from reproductions on Milesian coins, was also carried to Persia, there to remain till restored by Seleucus I in 295, and the oracle ceased to speak for a century and a half. The Milesians were not able to undertake the rebuilding till about 332 B.C., when the oracle revived at the bidding of Alexander. The work proved too costly, and despite a special effort made by the Asian province nearly 400 years later, at the bidding of the emperor Caligula, the structure was never quite finished, but even as it was, Strabo ranked the Didymaeum the greatest of Greek temples and Pliny placed it among the four

most splendid and second only to the Artemisium at Ephesus. The area covered by the platform measures roughly 360X160 feet.

No excavation was attempted till M. E. Pontremoli and B. Haussoullier were sent out by the French Schools of Rome and Athens in 1905. They cleared the western façade and the *prodomos*, and discovered inscriptions giving information about other parts which they left still buried. Finally the site was purchased by them, and the French rights were ceded to Dr. Th. Wiegand, the German explorer of Miletus, who in 1905 began a thorough clearance of what is incomparably the finest temple ruin in Asia Minor.

The temple was a decastyle peripteral structure of the Ionic order, standing on seven steps and possessing double rows of outer columns 60 ft. high, twenty one in each row on the flanks. It is remarkable not only for its great size, but (*inter alia*) for (1) the rich ornament of its column bases, which show great variety of design, (2) its various developments of the Ionic capital, e.g., heads of gods, probably of Pergamene art, spring from the "eyes" of the volutes with bulls' heads between them, (3) the massive building two storeys high at least, which served below for *prodomos*, and above for a dispensary of oracles *λειτουργία* mentioned in the inscriptions) and a treasury, two flights of stairs called "labyrinths" in the inscriptions, led up to these chambers, (4) the pylon and staircase at the west, (5) the frieze of Medusa heads and foliage. Two outer columns are still erect on the north east flank, carrying their entablature, and one of the inner order stands on the south west.

See Dilettanti Society, *Iohann Antiquities* II (1821), C. T. Newton, *Hist. of Discoveries* etc. (1862) and *Travels in the Levant*, II (1865), O. Rayet and A. Thomas, *Milet et le Golfe Latmique* (1877), E. Pontremoli and B. Haussoullier, *Didymes* (1904).

DIDYMIUM, originally regarded as a chemical element, was found by A. von Welsbach in 1885 to be a mixture of the two elements, praseodymium (*qv*) and neodymium (*qv*). (See also RARE EARTHS.)

DIDYMUS (309?-394), surnamed "the Blind," ecclesiastical writer of Alexandria, was, in spite of becoming blind at the age of four, one of the most learned men of his day, respected by Jerome and Athanasius. He became head of the catechetical school of Alexandria. He was condemned by the sixth and seventh general councils as a continuator of Origen, but he stoutly opposed Anan and Macedonian teaching. His surviving writings show a remarkable knowledge of Scripture, and have distinct value as theological literature. They include the *De Trinitate*, *De Spiritu Sancto* (Jerome's Latin trans.), *Adversus Manichaeos*, and expositions of various books, especially the Psalms and the Catholic Epistles.

See *Migne, Patrol. Graec.* xxxix, J. Lepoldt, "Didymus der Blinde" in *Texte u. Untersuchungen zur Gesch. der altchristl. Lit.*, vol. xiv (Leipzig, 1906), Thierot, *Hist. of Dogma*, vol. II (1914).

DIDYMUS CHALCANTERUS (c. 63 B.C.-A.D. 10), Greek scholar and grammarian, flourished in the time of Cicero and Augustus, and taught in Alexandria and Rome. His surname, which means "brass-bowelled," came from his industry, he was said to have written more than 3,500 books. He wrote a treatise on Anaxarchus' recension of Homer, of which fragments have been preserved in the Venetian Scholia. He also wrote commentaries on many other Greek poets and prose authors, and the extant scholia to Pindar, Sophocles and Aristophanes are largely due to Didymus. His work, though it showed no great critical acumen, was valuable because it collected the results reached by earlier scholars (Ammanius Marcellinus, xxii 16).

See M. W. Schmidt (*De Didymo Chalcantero* (1893)) and *Didymi Chalcanters fragmenta* (1894), also F. Susseml, *Geschichte der griech. Literatur in der Alexandrinerzeit*, II (1891), J. E. Sandys, *History of Classical Scholarship*, I (1906).

DIE, a town of south-eastern France, capital of an arrondissement in the department of Drôme, 43 m. ESE of Valence on the Paris-Lyons railway. Pop. (1936) 3,175. Under the Romans, *Die* (*Dea Augusta Voconiorum*) was an important colony. It was formerly the seat of a bishopric, united to that of Valence

from 1276 to 1687 and suppressed in 1790. Previous to the revocation of the Edict of Nantes in 1685 it had a Calvinistic university. The town stands in a plain enclosed by mountains on the right bank of the Drôme below its confluence with the Mey rose, which supplies power to some of the industries. The old cathedral has a porch of the 11th century supported on granite columns from an ancient temple of Cybele, and the Porte St. Marcel is a Roman gateway flanked by massive towers. There are also ruins of Roman aqueducts and altars. Die is the seat of a sub-prefect, and of a tribunal of first instance. The manufactures are silk, cloth, lime and cement, and there are saw mills. Trade is in timber, especially walnut, and in white wine known as *clarette de Die*. The mulberry is largely grown for the rearing of silkworms.

DIE, a word used in various senses for a small cube of ivory, etc. (see DICE), for the engraved stamps used in coining money, etc., and various mechanical appliances in engineering. In architecture a "die" is the term used for the square base of a column, and it is applied also to the vertical face of a pedestal or podium.

The fabrics known as "dice" take their name from the rectangular form of the figure. The original figures would probably be perfectly square, but to day the same principle of weaving is applied, and the name dice is given to all figures of rectangular form. The different effects in the adjacent squares or rectangles are due to precisely the same reasons as those explained in connection with the ground and the figure of damasks (*qv*).

The same weaves are used in both damasks and dices, but simpler weaves are generally employed for the commoner classes of the latter. The effect is, in every case, obtained by what are technically called warp and weft float weaves. The illustration B shows the two double damask weaves arranged to form a dice pattern, while A shows a similar pattern made from two four-thread twill weaves. C and D represent respectively the disposition of the threads in A and B from the first pick, and the solid marks represent the floats of warp. The four squares, which are almost as pronounced in the cloth as those of a chess-board, may be made of any size by repeating each weave for the amount of surface required. It is only in the finest cloths that the double damask weaves B are used for dice patterns, the single damask weaves and the twill weaves being employed to a greater extent.

This class of pattern is largely employed for the production of table cloths of low and medium qualities. The term damask is often applied to cloths of this character, and especially so when the figure is formed by rectangles of different sizes.

DIEBITSCH, HANS KARL FRIEDRICH ANTON (1785-1851), Count von Diebitsch und Narden, called by the Russians Ivan Ivanovich, Count Diebich Zabalinskij, Russian field marshal, was born at Grosspriepe, Silesia, on May 13, 1785. He was educated at the Berlin cadet school, but passed into the service of Russia in 1801. He served in the campaign of 1805, and was wounded at Austerlitz, fought at Eylau and Friedland, and after Friedland was promoted captain. He distinguished himself very greatly in Wittgenstein's campaign, and in particular at Polotsk (Oct. 18 and 19, 1812), and was promoted major general. In the latter part of the campaign he served against the Prussian contingent of Gen. York (von Wartenburg), with whom, through Clausewitz, he negotiated the convention of Tauraggen serving thereafter with York in the early part of the War of Liberation. After the battle of Lutzen he served in Silesia and took part in negotiating the secret treaty of Reichenbach. He fought at Dresden and Leipzig. At the crisis of the campaign of 1814 he urged the march of the allies on Paris. In 1815 he attended the congress of Vienna, and was afterwards made adjutant general

DICE PATTERNS SHOWING WEAVES. A is formed from two four thread twill weaves. B from two double damask weaves. C shows the arrangement of the warp and weft in A, while D shows the arrangement of B.

to the emperor. In 1806 he had become chief of the general staff and in 1825 he assisted in suppressing the St. Petersburg *revolutions*. His greatest exploits were in the Russo-Turkish War of 1828-29 which was decided by Diebitsch's brilliant campaign of Adrianople, this won him the rank of field marshal and the honorary title of Zabalanskii to commemorate his crossing of the Balkans. In 1830 he was appointed to command the army destined to suppress the insurrection in Poland. He won the terrible battle of Grochow on Feb. 25, and was again victorious at Ostolenska on May 26, but soon afterward he died of cholera (or by his own hand) at Klekewo near Pultusk, on June 10, 1831.

DIEDENHOFEN see THIONVILLE

DIEKIRCH, a small town of Luxembourg, situated on the banks of the Sure. Pop. (1935) 3,842. Its name is said to be derived from Dido or Dido, granddaughter of Odin and niece of Thor. Diekirch was an important Roman station, and in the 14th century John of Luxembourg, king of Bohemia, fortified it. In the 19th century during their occupation the French changed the fortifications into boulevards.

DIELECTRIC see CONDENSER [ELECTRICAL] and ELECTRICITY

DIELMANN, FREDERICK (1847-1915), U.S. portrait and figure painter, was born at Hanover, Ger., Dec. 25, 1847. He was taken to the United States in early childhood, studied under Diez at the Royal academy at Munich, was first an illustrator, and became a distinguished draughtsman and painter of genre pictures. His mural decorations and mosaic panels for the Library of Congress, Washington, D.C., are notable. He was president of the National Academy of Design (1899-1909), president of the Fine Arts Federation of New York (1910-15), professor of art at the College of the City of New York (1905-18) and art director of Cooper Union, New York city (1905-31).

DIEMEN, ANTHONY VAN (1593-1645), Dutch admiral, became governor general of the East Indian settlements in 1636, and captured the Portuguese possessions in Ceylon and Malacca. He developed the prosperity both of the Indies and of Dutch trade with them, ensuring the Dutch monopoly, e.g., of pepper in Sumatra, etc. He greatly extended the commercial relationships of the Dutch, opening up trade with Tongking, China and Japan. Exploring expeditions were sent to Australia under his auspices in 1636 and 1642, and Abel Tasman named after him (Van Diemen's land) the island now called Tasmania. Van Diemen died at Batavia on April 19, 1645.

DIEPPE, a seaport of northern France, capital of an *arrondissement* in the department of Seine Inférieure, on the English channel, 38 mi. N. of Rouen, and 105 mi. NW. of Paris by the Western railway. Pop. (1946) 21,770. It is suggested that Dieppe owed its origin to Norman adventurers, who found its 'diep' or inlet suitable for their ships, but it was unimportant till the late 12th century.

Its first castle was probably built in 1188 by Henry II of England, and Philip Augustus attacked it in 1195. In 1197 it was bestowed by Richard I of England on the archbishop of Rouen in return for territory near the latter city. In 1339 it was plundered by the English, but soon recovered, and, in spite of opposition from the lords of Hantot, fortified itself. Its commercial activity was already great. It is believed that its seamen visited the coast of Guinea in 1339, and founded there a Petit Dieppe in 1365.

The town was occupied by the English from 1420 to 1435. A siege undertaken in 1442 by John Talbot first earl of Shrewsbury, was raised by the dauphin, afterward Louis XI, and the day of the deliverance continued for centuries to be celebrated by a great procession and miracle plays. In the beginning of the 16th century Jean Parmentier, a native of the town, made voyages to Brazil and Sumatra, and a little later its merchant prince, Jacques Ango, was able to blockade the Portuguese fleet in the Tagus. Francis I began improvements, continued under his successor. Its inhabitants in great number embraced the reformed

religion and they were among the first to acknowledge Henry IV, who fought one of his great battles at the neighbouring village of Arques. Few cities suffered more from the revocation of the edict of Nantes in 1685, and this blow was followed in 1694 by a terrible bombardment on the part of the English and Dutch. The town was rebuilt after the peace of Ryswick, but its modern prosperity dates only from the 19th century, partly because of Marie Caroline, duchess of Berry who brought it into fashion as a watering place, and also because the railway gave an impetus to its trade.

During the Franco-German War the town was occupied by the Germans from Dec. 1870 till July 1871. It stands at the mouth of the river Arques in a valley bordered on each side by steep white cliffs. The main part of the town lies to the west, and the fishing suburb of Le Pollet to the east of the river and harbour.

The sea front of Dieppe, which in summer attracts large numbers of visitors, consists of a pebbly beach backed by a broad some marine promenade. Dieppe has a modern aspect, and two squares built by side and immediately to the west of the outer harbour form the nucleus of the town. The church of St. Jacques, founded in the 13th century, consists largely of later work. The castle was restored in the 19th century. The castle, overlooking the beach from the summit of the western cliff, was built in 1435. The church of Notre Dame de Bon Secours on the opposite cliff, and the church of St. Remy, of the 16th and 17th centuries, are noteworthy. A well equipped casino stands on the sea front.

The public institutions include the subprefecture, tribunals of first instance and commerce, a chamber of commerce and a school of navigation.

Dieppe has one of the safest and deepest harbours on the English channel. A curved passage cut in the bed of the Arques and protected by an eastern and a western jetty gives access to the outer harbour, which communicates at the east end by a lock gate with the Bassin Duquesne and the Bassin Berigny, and at the west end by the New channel with an inner tidal harbour and two other basins. Vessels drawing 20 ft. can enter at neap tide. A dry dock and a grondron are among the repairing facilities of the port. The harbour railway station is on the northwest quay of the outer harbour.

The distance of Dieppe from Newhaven, with which there has long been daily communication, is 64 mi. The imports include silk and cotton goods, thread, oils, timber, coal, iron, patent fuel cement, china clay, machinery, tobacco and mineral oil, leading exports are wine, silk, woollen and cotton fabrics, vegetables and fruit and flint pebbles. The industries comprise shipbuilding, oil refining, steam sawing, the manufacture of machinery, rope, porcelain, briquettes and articles in ivory and bone, the production of which dates from the 15th century. The fishermen of Le Pollet, traditionally of Venetian origin, are among the main providers of the Parisian market. The sea bathing attracts many visitors in the summer.

Two miles to the northeast of the town is the ancient camp known as the Côte de Limes, which perhaps furnished the nucleus of the population of Dieppe.

See L. Vitet, *Histoire de Dieppe* (Paris, 1844); D. Asseline, *Les Antiquités et chroniques de la ville de Dieppe*, a 17th century account published at Paris in 1874.

DIERX, LEON (1838-1912), French poet, was born on the island of Réunion in 1838, and died in Paris on June 11, 1912. He came to Paris to study at the Central School of Arts and Manufactures. A friend and disciple of Leonote de Lisle, Dierx was one of the most distinguished of the Parnassians. On the death of Stéphane Mallarmé in 1898 he was acclaimed 'prince of poets' by 'les jeunes'. The most significant of his volumes of verse is *Lèvres closes* (1867). His *Oeuvres* (2 vol., 1894-96) contain much exquisite verse.

DIESEL, RUDOLF (1858-1913), German engineer, was born in Paris, March 18, 1858, of German parents. He was educated at the Munich Polytechnic school and spent a short time in Paris as manager of a company which manufactured refrigerating equipment, but returned to Munich, where in 1885 he

published *The Theory and Construction of a Rational Heat Motor*, the result of his studies on what was to become the diesel oil engine. In the same year work began at the Kupp and Augsburg machine factories on the construction of the diesel engine (qv). Work continued on the motor until 1897, and in 1898 it was publicly displayed for the first time at Munich. In 1899 Diesel founded a factory for the construction of the engines at Augsburg and spent the greater part of the rest of his life perfecting the machine, although he did not live to see its possibilities fully exploited. On the night of Sept. 29-30, 1913, he fell overboard from the Antwerp Harwich mail steamer in the English channel and was drowned. In the last year of his life he wrote *The Genesis of Diesel Motors*.

For a discussion of the practical uses of Diesel's invention, see ALBRO ENGINES MARINE ENGINEERING, LOCOMOTIVE

DIESEL ENGINE In 1892 Rudolf Diesel, a German engineer, patented a type of internal combustion engine which became inseparably associated with his name. His first successful engine was a 25 hp unit completed in 1897 and tested by Schroter at Augsburg, Ger., in the same year. Diesel engines were exhibited publicly for the first time in 1898 at the Munich exhibition.

The diesel engine was taken to the United States in 1898 by Adolphus Busch of St. Louis, Mo., who paid Diesel 1,000,000 gold marks for patents and exclusive manufacturing and sales rights in the United States and Canada. Busch formed the Diesel Motor Company of America in 1898, he later changed its name to American Diesel Engine company, since the word motor was an apparent misnomer when applied to diesels. In 1898 this company built the first successful diesel in the world to operate commercially in regular power service.

In 1900, Diesel announced before the congress at Paris that the cycle of operations finally adopted by him after extended experiments was as follows:

- 1 A suction stroke during which air alone at atmospheric pressure was drawn into the cylinder
- 2 A compression stroke in which this air was next compressed to a pressure of 500-600 lb per square inch
- 3 From the end of the compression stroke, and for a short period after, regulated admission of the fuel in the form of a fine spray in such manner as to cause combustion to occur at (approximately) constant pressure
- 4 Expansion of the ignited mixture of fuel spray and air during the remainder of the working stroke
- 5 Expulsion of the burned products during the next stroke

The cycle thus described was of the four-stroke type with a stroke sequence of suction, compression, expansion and exhaust. The first diesels were air injection engines that used high pressure compressors to inject the fuel supply into the engine cylinder with a blast of air. In 1910 James McKechnie of England developed an airless or solid-injection system which used a simple high pressure fuel oil pump for injection purposes. The solid-injection system became the predominant method of fuel injection about 1930. Irrespective of its fuel system the essential feature of the diesel cycle is the compression of atmospheric air to a pressure of about 500 lb per square inch which raises the air temperature to about 1,000° F. A controlled amount of atomized oil is injected into the highly compressed red-hot air, causing it to ignite spontaneously, burn and expand. Thus, no ignition apparatus is required with an engine that operates on the true diesel cycle.

Definition of a Diesel Engine—A diesel engine is defined as an internal combustion engine so constructed that the air supplied for combustion is compressed within the engine cylinder to the point where its temperature is sufficient to ignite the injected fuel spontaneously.

The spark-ignition gasoline engine differs from the compression-ignition diesel engine in the nature of the fuel charge. Gasoline and air are thoroughly mixed in the cylinder of the spark-ignition engine and this homogeneous mixture is introduced into the engine cylinder in a definite proportion regardless of load. The proportion of air to fuel, called the air-fuel ratio, is constant for gasoline engines in the ratio of 14.5:1, i.e., 14.5 lb of air to 1 lb of fuel. Since the diesel has no equivalent burning chamber for air and fuel oil, the mixing must be accomplished within the

cylinder itself. The diesel always compresses the same amount of air while the amount of injected fuel is varied to suit the load conditions. Thus the air-fuel ratio varies from about 22:1 at full load to about 85:1 when the engine is idling. The diesel engine requires an excess amount of air as compared to the gasoline engine. High air-fuel ratios and high compression pressures give the diesel its advantage in fuel economy and it is not unusual to find a diesel motored vehicle giving double the fuel mileage as compared with a similar gasoline motored vehicle. A further advantage is its ability to burn a cheaper fuel and to enjoy a lessened fire hazard.

Operating Cycles—Diesel engines operate on either the four stroke or the two stroke cycle. Basically, this means that the four stroke cycle engine requires four complete strokes of the piston or two revolutions of the crankshaft to complete one operating cycle while the two stroke cycle engine completes this sequence in two piston strokes or in one revolution of the crankshaft. The two extra strokes in the four-stroke cycle engine are used to get fresh air into and exhaust gases out of the cylinder. The two stroke cycle engine eliminates these strokes by substituting a scavenging period during which the spent exhaust gas is blown from the cylinder and replaced by a fresh charge of air. Scavenging then, requires an external source of low pressure air.

The stroke sequence of the four stroke cycle engine is illustrated in fig. 1.

1 INTAKE 2 COMPRESSION 3 POWER 4 EXHAUST
FIG. 1—SCHEMATIC VIEW OF A FOUR-STROKE CYCLE DIESEL ENGINE ILLUSTRATING THE SEQUENCE OF CYCLE EVENTS

The four-stroke cycle engine operates as follows: (1) intake the inlet valve opens and the descending piston draws a fresh charge of air into the cylinder, (2) compression the inlet valve closes and the rising piston compresses air within the cylinder to a pressure of about 500 lb per square inch, (3) power toward the end of the compression stroke fuel is injected, it ignites spontaneously and expands, thus forcing the piston down through the power or expansion stroke, (4) exhaust the exhaust valve opens and the rising piston forces the burned gases out of the cylinder, the cycle then repeats.

The sequence of events in a two-stroke cycle, port scavenged engine is illustrated in fig. 2. Scavenging air is maintained in the air header at a pressure of a few pounds above the atmospheric pressure by a blower, not shown.

1 INTAKE 2 COMPRESSION 3 POWER 4 EXHAUST
FIG. 2—SCHEMATIC VIEW OF A TWO-STROKE CYCLE DIESEL ENGINE ILLUSTRATING THE SEQUENCE OF CYCLE EVENTS

The two stroke cycle engine operates as follows: (1) intake the descending piston uncovers the inlet and exhaust ports and scavenging air enters the cylinder from the inlet port, flushes the

cylinder, and leaves via the exhaust port, (2) compression the rising piston covers both the inlet and exhaust ports and compresses the air in the cylinder to a pressure of about 500 lb per square inch, (3) power a charge of fuel is injected into the highly heated air, it ignites spontaneously and expands, forcing the piston down through the power stroke, (4) exhaust the descending piston uncovers the exhaust and inlet ports, scavenging air under pressure enters through the inlet port and forces the burned gases to leave the cylinder via the exhaust port, thus completing the cycle.

The ideal two cycle engine would develop twice the power of a four cycle of equal size and speed, actually, the ideal is not achieved since the two cycle has a less effective stroke because of the presence of ports in the cylinder. The two cycle does, however, possess important advantages over the four cycle, particularly in the larger size engines, in that it is lighter for the same power output, has fewer moving parts and is simpler. These characteristics give the two and four cycle engines their particular fields of application. The tendency is to build the large engines two cycle and the smaller engines four cycle. There is, of course, an overlapping of sizes in both cycles with very high grade engines of each type being built.

Scavenging air is supplied to two cycle engines by reciprocating pumps, blowers, or by means of the crankcase scavenging method. Crankcase scavenging was widely used in early two stroke cycle engines up to 100 h.p. per cylinder and found favour because of its simplicity and its low initial and maintenance costs. The crankcase scavenging engine was, however, found to be less economical and had a lower power output than some engines using later scavenging developments. The underside of the engine's power pistons, the cylinders and the crankcase form a low pressure compressor. Fresh air is drawn into the crankcase as the piston upstroke and is compressed within the crankcase as the piston descends. Suitable port arrangement releases air from the crankcase for scavenging. Reciprocating scavenging pumps are usually large diameter, double acting, attached units, actuated by a connecting rod from a crank extension of the engine crankshaft. The pumps are simple low pressure compressors and are used in successful engines of modern design. Scavenging blowers of the Roots type are positive displacement blowers, usually attached and gear or chain driven from the engine. Centrifugal scavenging blowers are fanlike in principle and because of their high operating speeds are usually driven by a turbine or electric motor and are not usually built as an integral part of the engine. The air discharge from either pump or blower is delivered to an air manifold where the engine cylinders receive their supply of scavenging air. The method of admittance and the path of scavenging air through the engine cylinder is determined by various arrangements of ports or valves or combination of both. In uniflow scavenging, air is admitted through ports at the lower end of the cylinder and exhaust is forced out through valves at the upper end. The uniflow type system is used in both high- and low speed engines of modern design. The all ported cylinder which provides the simplest and most widely used method of scavenging is shown in fig 3. Inclined air ports direct scavenging air in a loop path as indicated by arrows in fig 3. Automatic feather type scavenging valves, located in the air header, allow scavenging air to flow in the out direction only, to prevent exhaust gas from entering the header and contaminating the fresh air supply.

Diesel Construction—Designs and sizes of diesel engines had not been standardized in either Europe or the United States by mid-20th century. Different designs reflected the individual opinions of various diesel manufacturers. As a result, the engine had been built in many sizes and each operated in different speed classifications and assumed different general design and constructional form. The cylinder arrangement might be in-line, radial, V, X, or of the opposed piston, the usual single-acting or even the double acting type. In either two- or four-cycle, the engines might have individual cylinders and columns or be built en bloc. Two cycles have variations of air flow caused by different port and valve arrangements. Diesels might have trunk pistons or cross-

FIG 3—SECTIONAL VIEW OF A TWO STROKE CYCLE PORT SCAVENGED ENGINE. ARROWS INDICATE SCAVENGING AIR PATH.

heads be supercharged and intercooled or not. They might operate on varying types of gaseous fuels such as natural gas, illuminating, producer, blast furnace, or sewer gas, or on varying types of fuel oils from heavy crudes through the range to lighter distillates, or even on both gaseous and oil type fuels. Various engines might use turbulence or precombustion chambers, air or energy cells or be of the open chamber design. All designs were compromise, and each manufacturer was building diesels for certain broad fields of application.

The diesel was practically unknown to the public until it made its appearance in trucks, buses and railroad locomotives. Other applications, however, had become equally important but not as apparent. Diesels are used to drive ships, generators, pumps, compressors, mills, rock crushers, earth moving machinery, tractors and for many other purposes where economy and dependability are requisite. Each application determines certain design characteristics. Although diesels have been classified by various methods, the most common grouping is by relative speed. There was little agreement at mid century as to what constituted a high or low speed diesel but for purposes of convenience the following arbitrary classification is established. Engines that operate above 1,200 r.p.m. will be referred to as high speed engines, those operating below 500 r.p.m. will be classified low speed engines, and those in the range between these limits will be termed medium speed engines.

High speed diesels are essentially small bore engines, 6 in. and under, built to compete with gasoline engines in both physical dimensions and power output. Cylinder arrangement is usually in line or of the V type. The auxiliaries such as electric starters, lube oil pumps, water pumps and cooling systems are contained as an integral part of the engine. The engine is seldom if ever built as a direct reversing unit and where reversing is required it is accomplished through an attached reverse gear. High-speed engines frequently use turbulence chambers, air or energy cells to facilitate fuel combustion. There is seldom any provision for auxiliary piston cooling. This size engine develops a maximum of about 30 h.p. per cylinder and uses a light grade diesel oil for fuel.

Medium speed diesels embrace the largest single group in the classification, having cylinder bores in a range from 6 to 14 in. The engine may be built in any of the previously mentioned cylinder arrangements, radial, in line, V, X, etc. Medium speed engines usually have attached auxiliaries. They may be started electrically, started by a small attached gasoline engine, or be air started. When reversing is required the engine may be constructed for direct reversing or have an attached reverse gear.

Diesels of this size went through the auxiliary combustion chamber stage, but open type chambers were generally preferred at mid century. Pistons are usually cooled by means of an oil spray directed at the underside of the piston head. Engines of this size develop between 30 and 700 h.p. per cylinder. Appropriate design enables individual engines to burn any of a variety of fuels of the gaseous or oil types.

Low speed diesels include the largest built, having cylinder bores ranging upward from 14 in. in diameter. The smaller bore size of low speed diesels may have any one of the cylinder arrangements, but the larger bore engines, 20 in. and up, are usually built in an in line arrangement. Auxiliaries are sometimes contained as an integral part of the engine but are usually separated from the engine proper in large installations. Air starting systems are invariably used. Where reversing is required the engine rarely operates through a reverse gear and is usually constructed as a direct reversing unit. Auxiliary combustion chambers are never used. Pistons are always cooled, the forced oil system being preferred. The power rating per cylinder is upward from 200 h.p. Any type of fuel may be burned, and combustion efficiency is always best in well designed engines of large size.

Fig 4 shows a cross section through the power cylinder of a medium speed four cycle engine. The unit illustrated in fig 4 is typical of four cycle design. A one-piece bedplate forms the foundation on which the engine is built. A forged steel crankshaft rotates in main bearings that are lined with soft bearing metal and pressure lubricated for long life. The cast frame is secured to the bedplate by tie rods. A removable cylinder is contained in the frame and has ample water jackets for efficient cooling. An oil cooled trunk type piston reciprocates in the cylinder liner and translates its motion through a forged steel connecting rod to the crankshaft. A water jacketed cylinder head seals the combustion end of the cylinder and contains the injection nozzle, the inlet, exhaust and starting air valves.

FIG 4—SECTIONAL VIEW OF A MODERN MEDIUM SPEED FOUR STROKE DIESEL ENGINE

A cross sectional view through the power cylinder of a large single-acting two-cycle diesel built in the United States is illustrated in fig 5.

Although its size precludes many specialized manufacturing problems, the general design is typical of large low-speed heavy-duty two-cycle engines. The piston is built in two pieces and has a separate pistonhead to facilitate efficient oil cooling. Attached to the connecting rod is a crosshead travelling in guides which

FIG 5—SECTIONAL VIEW OF A MODERN LOW SPEED PORT SCAVENGED TWO STROKE CYCLE DIESEL ENGINE

absorbs the side thrust caused by the angularity of the connecting rod. The piston is attached to the crosshead and since it bears no side thrust it may be proportionally shorter than the corresponding piston of a trunk type engine. Fig 4 is an example of trunk type piston construction. A bedplate supports a series of individual A columns which, in turn, support individual cylinder blocks. These major parts are held together with tie rods to form a rigid unit. The similar elements in fig 4 and fig 5 perform identical functions, and the constructional variation other than that required for two- and four cycle operation is due primarily to size difference. The specific power output of the large engine is nearly 14 times greater than the smaller one.

Supercharging—When an amount of air in excess of the normal displacement volume is introduced into an engine cylinder under pressure and is retained at the start of the compression stroke, the engine is said to be supercharged. Scavenging air under pressure is supplied to all two cycle cylinders and it would seem, therefore, that all engines of this type are supercharged, actually, however, they are not, unless a portion of this more dense air is retained at the start of compression.

The power output of an engine is limited by the amount of oxygen, *i.e.*, air that can be taken into its cylinders per stroke. With additional air available for combustion, the engine is able to burn a greater amount of fuel, and its power output is increased. There are two ways of increasing an engine's breathing capacity: (1) increase the rotative speed, *i.e.*, fill the cylinders more frequently, and (2) force more air into the same cylinder space by means of pressure, *i.e.*, supercharging. In the evolution of the diesel engine these paths were explored and both speeds and operating pressures became increasingly greater.

The barrier to higher speeds for automotive types, and to even greater efficiency for all diesels, is the difficulty in mixing the fuel spray intimately with the air. Imperfect mixing delays fuel ignition and tends to impair combustion efficiency. Although these effects are aggravated as speeds go higher, modern automotive-type diesels, where revolutions per minute is important, have been developed to the point where they attain good efficiencies at speeds of about 3,000 r.p.m.

Special port, valve and blower arrangement is required in both

two and four cycle engines to provide a supercharging effect. Two cycle supercharge rarely exceeds two to four pounds per square inch above atmospheric pressure. Beyond this the blowers absorb more power than they provide. Four cycle supercharge ranges from 3 to 15 lb per square inch and provides an increase in power output from 30% to 80%, with 50% being a conservative figure. Engines are supercharged for two reasons: (1) to increase power output for a given sized engine and (2) to provide the additional air required to sustain power output in the less dense air at high altitudes.

Supercharging blowers may be driven mechanically or by means of an exhaust gas turbine. The mechanically driven blower may operate directly from the engine or be separately driven from another power source. The most efficient supercharging method utilizes part of the exhaust gas energy to drive a gas turbine that is directly connected to a blower. This type of turbocharger system was applied by Alfred V. Buchi of Switzerland. The Buchi system uses special valve timing in combination with multiple exhaust manifolding, and is able to attain a substantial power increase (50% is common), with no increase in specific fuel consumption. Supercharging effect is sometimes increased by the addition of an intercooler located between the supercharger and intake air manifold. Its function is to cool the inlet air and thereby increase its density so that additional fuel can be burned. Like supercharging, intercooling increases the power capacity of an engine of given displacement.

Diesel Auxiliaries—Fig. 6 shows a view of the auxiliary equipment used in a typical, large stationary diesel plant. While individual plant conditions determine the specific location of auxiliaries, their respective functions remain the same.

The auxiliary equipment may be divided into the following systems: lubricating oil (called lube oil), cooling water, fuel, governor, inlet, exhaust and starting air.

The *lube oil system* consists of a filter, a strainer, an oil cooler and two oil pumps. The lube oil pump draws oil from the sump, sends it through the strainer, the cooler and then forces oil under pressure to various bearing surfaces. The lubricant drains from the engine and collects in the sump. The lube oil filter pump continually recirculates a portion of the sump oil and forces it through a filter.

The *cooling system* consists of a cooling tower, a water pump and a heat exchanger. The closed circuit type system is illustrated in fig. 6 and is usually recommended because of its comparatively small water requirement and further, because the circulating jacketwater may be treated to eliminate scale forming agents. Cooling water is pumped into the cylinder jacket, flows through the cylinder head and out of the engine into a heat ex-

changer. The heat exchanger cools the jacket water which is then passed through the oil cooler. Cool water is continually pumped from the cooling tower through the heat exchangers.

The *fuel system* consists of a large storage tank, a smaller day tank, and the necessary filters, strainers and pumps to insure that clean oil is supplied to the high pressure or fuel injection pumps. The system illustrated in fig. 6 is for oil operation.

The *governor* is a sensitive device that controls and maintains the engine speed at a constant level by regulating the amount of fuel that is admitted into the engine cylinder.

The *inlet air system* consists of piping from a source of fresh air leading to the engine air header. A filter is provided to remove harmful grit and dust from the inlet air.

The *exhaust system* consists of piping from the engine leading to the outside atmosphere where exhaust gases can be of no danger. An exhaust silencer or muffler is provided to reduce engine exhaust noises. A waste-heat boiler, not shown in fig. 6 may be added to the exhaust system so that some of the heat from exhaust gases can be recovered for use.

The *starting air system* consists of a compressor, air storage tank, piping and a means of timing the admission of compressed air to the engine cylinder.

Gas Diesel—The gas diesel was developed in the United States in 1928 and is capable of burning any form of combustible gas in combination with a small amount of pilot oil. Pilot oil is injected to ignite and stabilize the combustion of the compressed gas-air mixture. There are two methods of getting gas into the two cycle cylinder. It may either be admitted under low pressure immediately after scavenging, or it may be compressed to about 1,000 lb per square inch and forced into the cylinder as the piston approaches the end of its compression stroke. When a diesel is arranged to operate on either gas or oil or a combination of both fuels it is called a dual-fuel diesel, which may be either two or four cycle.

Fig. 7 shows a sectional view of a four cycle dual-fuel diesel that can convert instantaneously under load from oil to gas or from gas to oil operation. It is capable of running on any proportion of either fuel down to 5% of oil, an adjustment that is made by simply turning a single control wheel. The operation is as follows: an engine governor interprets the load requirement and regulates the flow of low-pressure gas fuel to a gas header. Individual gas and inlet air valves open simultaneously at the start of the intake stroke to admit and thoroughly mix the entering air and gas. All valves are closed on the next stroke as the rising piston compresses the combustible mixture to about 500 lb per square inch. Toward the end of the compression stroke pilot oil is injected and the mixture ignites and expands. The

FIG. 6—SCHEMATIC VIEW SHOWING THE AUXILIARY EQUIPMENT USED IN A TYPICAL STATIONARY DIESEL PLANT

remains of the cycle proceeds as in the four stroke oil burning diesel. While Fig. 7 illustrates one method of four cycle dual fuel

FIG. 7—SECTIONAL VIEW OF A FOUR STROKE CYCLE DUAL FUEL DIESEL ENGINE

operation there were other successful means in general use at mid century. The main variation is the method in which the gas is introduced into the cylinder. Regardless of the method of admittance, gas injection is always timed to prevent its being wasted during scavenging.

Fuel Oil Injection—After the conception of the diesel engine, fuel injection equipment became the subject of intensive research and development as a means of further increasing combustion efficiency. Two principal methods of fuel injection were in use at mid-century: air injection and solid injection. In air injection, the earliest successful method a metered quantity of fuel is delivered to the nozzle by a fuel pump and blown into the combustion chamber by compressed air at 700 to 1,400 lb. per square inch when an actuated nozzle valve is lifted. This system was still sometimes used at mid-century in large low speed engines operating on heavy crudes, but was no longer popular for use with light oil-fuels because of the expense, bulk and hazards of the com-

between the pump and spray nozzle.

Two basic types of spray nozzles have been developed to suit different combustion chamber designs. Pintle type nozzles produce a cone shaped spray and are used in engines with pre-combustion, divided or air cell chambers, hole type nozzles are used in open chambers and produce a relatively dense and compact fuel spray. Nozzles are also classified as open or closed. The open type consists of a plug with drilled fuel passages and orifices. Although it is simple it is susceptible to poor atomization at the beginning and end of each injection. The closed type came into more general use as it has its fuel passages sealed from the orifices by a spring loaded valve which is opened during injection either mechanically from the engine cams or hydraulically by oil pressure from the fuel pump.

Fig. 8 shows a cross section of the main components of a popular commercially jerk pump system.

The single cylinder pump is of the constant stroke variable by pass type in which the plunger with its follower and return spring, is actuated by an engine cam. The pump delivers oil when the plunger covers the fuel inlet ports on its upstroke. The quantity of fuel injected is varied by changing the effective plunger stroke by turning the plunger so as to change the time of by-pass, i.e., by-pass occurs when the upper helical edge of the wide plunger groove uncovers the spill port. Fuel delivery then ceases, and the seating of the special delivery valve retracts fuel from the discharge tubing to sharply terminate injection. The nozzle and holder assembly incorporates a nozzle of the multifluid, closed, hydraulically operated type. From the inlet at the top, fuel is led through drilled passages to an annular groove surrounding the stepped portion of the valve above its conical seat. Fuel pressure acts on the exposed cross sectional area of the valve and lifts it so that fuel is injected during the period that the fuel oil pressure exceeds the spring setting.

Advantages of the Diesel—The inherent advantage of the diesel becomes more apparent when its heat efficiency is compared with other prime movers including steam turbines, gas turbines, steam engines and gasoline engines. The compression-ignition feature not only simplifies the diesel by eliminating a separate ignition system but is also directly responsible for its good heat or thermal efficiency. The average

FIG. 8—PLAN VIEW SHOWING THE COMPONENTS OF A JERK PUMP

of the diesel is about 36% as compared with 25% for steam and gas turbines, and 12% for internal combustion engines. These percentage figures are approximate to full load capacity. At partial loads the comparative efficiency is even greater.

DIESEL LOCOMOTIVE

DIESINKING, art of making tools, called *dies*, by means of which metals and other materials are pressed or cut into various shapes by a hammer or an arrangement of levers. The die is usually cut from steel by a machine, but where extreme accuracy is required (e.g., when engraving dies for coins, goldsmiths' work and for some parts of machines) handwork predominates. Here an exact copy of the design is traced on a thin coating of wax spread over the prepared smooth surface, and is then engraved on the metal by recessing or *sinking*. The tools used are chisels, gravers and rifflers, which are small files with curved ends for negotiating curves and recessed portions. First the sinker receives the master die by engraving in intaglio the design on a piece of soft steel called the *hub*, which is then hardened to form the *matrix*. By means of the matrix, the design is expressed in relief on a second piece of softened steel called the *punch* which in turn is hardened and held in the press to strike the softened face of the working die. Several operations are necessary to bring the impressions to a perfect state, the first blow being made on the die while in cone shape (see fig 1). The blow changes the form to that in the second view. The working die must then be annealed, and its edge turned off a little smaller, a complete, perfectly clean impression is produced, the die appearing as in the third view.

Considerable quantities of metal must be removed in sinking dies, and machine cutting, as far as possible, is essential to save hand labour. Dies which have the shape cut through from top to bottom for presswork, are roughed out on a metal jigsawing machine, and finished on a slotting machine or a bluing machine which passes a file up and down while the die is held on a table and moved about as required. Large dies are often cut out by means of the oxyacetylene blowpipe. A diesinking machine, which is a milling machine, uses a variety of revolving cutters (see fig 2). The difficulty with half dies, pairs of which make cylindrical or spherical shapes, is the cutting of the half round recesses. A *cherry cutter* is utilized for these, instead of revolving it is made to oscillate by the action of a curved slide on the

FIG 1—EVOLUTION OF COINING DIE

Dies for stamping coins are not actually cut by hand but are milled from a hardened matrix which has been struck from an engraved die. A number of heavy blows cause the matrix to impress its pattern upon the soft working die.

FIG 2—THREE MILLING CUTTERS. Milling cutters eliminate hand cutting. The die is moved about under the cutters as required by slides controlled with screws and handwheels.

FIG 3—CHERRY CUTTER AND CROSS SECTION OF A DIE CUT THROUGH IN THE VERTICAL DIRECTION. AS EACH END OF THE CONCAVITY IS CLOSED THE CHERRY CUTTER IS NECESSARY TO MILL OUT THE CURVE.

machine, this motion (not required in other metalworking operations) cutting a half round recess as sketched. The principle of

the copying lathe applied to the diesinking machine, enables it to cut any intricate shapes from a pattern in sheet metal, or sunk in iron or brass, the milling cutters being guided by the movement of an arm controlled by the pattern. Pinstriping engraving and diesinking machines also work from a copy, and cut the dies to an enlarged or reduced scale. A celluloid or sheet metal copy can be used also for guidance when cutting lettering, the copy being either in one piece or made up of the separate letters or figures clamped in a holder.

DIES IRAE (Lat. 'dies of wrath'), the opening words of a Latin hymn on the Last Judgment, ascribed to Thomas of Celano (c. 1250) and forming part of the office for the dead and requiem mass, in music the traditional plain song melody to which the words are sung and setting, in general of this portion of the mass. Among famous examples of the latter may be mentioned those of Mozart, Schubert, Beethoven and Verdi.

DIEST, a town in the province of Brabant, Belg., on the Demer at its junction with the Bever. Pop. (est. 1939) 8,499. The chief industry is brewing.

DIESTERWEG, FRIEDRICH ADOLF WILHELM (1790-1866), German educationist, was born at Siegen on Oct. 29, 1790. Educated at Herborn and Tübingen universities, he began teaching in 1811. In 1818 he was appointed director of the teachers' seminary at Mors where in practice the methods of J. H. Pestalozzi. In 1837 he became director of the new state schools seminary in Berlin. In 1846 he established the Pestalozzi institution at Pankow, and the Pestalozzi societies for the support of teachers' widows and orphans. In 1858 he was elected to the chamber of deputies as member for Berlin, and voted with the Liberal opposition. He died in Berlin on July 7, 1866. Diesterweg wrote several textbooks and educational works, including *Wegweiser für deutsche Lehrer* (1834), and in 1827 established *Rheinische Blätter für Erziehung u. Unterricht*.

See W. Kraatz, *Diesterweg und die Lehrerbildung* (1890), K. Richter, *Diesterweg nach seinem Leben und Wirken* (1890).

DIET, a term used in two senses: (1) food or the regulation of feeding (see DIET AND DIETETICS), and (2) an assembly or council. We are concerned here only with this second sense, and in particular with the diet of the Holy Roman empire and its relation to its successors in modern Germany.

The origin of the diet, or deliberative assembly of the Holy Roman empire, must be sought in the *placitum* of the Frankish empire. This represented the tribal assembly of the Franks meeting partly for a military review on the eve of the summer campaign, partly for deliberation on important matters of politics and justice. By the side of this larger assembly, however, which continued in theory, if not in practice, the whole body of Franks available for war, there had developed, even before Carolingian times, a smaller body composed of the magnates of the empire, both lay and ecclesiastical. The germ of this smaller body is to be found in the episcopal synods, which, afforded by the attendance of lay magnates, came to be used by the king for the settlement of national affairs. It is from this assembly of magnates that the diet of mediæval Germany springs. The general assembly became meaningless and unnecessary as the feudal army gradually superseded the old levy en masse, in which each free man had been liable to service, and after the close of the 10th century it no longer existed.

The imperial diet (*reichstag*) of the middle ages might sometimes contain representatives of Italy, but it was nearly always confined to the magnates of Germany. The regular members were the princes (*Fürsten*), both lay and ecclesiastical. In the 13th century the seven electors began to disengage themselves from the prince as a separate element, and the Golden Bull (1356) made their separation complete, from the 14th century onward the nobles (both counts and other lords) attended along with the princes, and after 1250 the imperial and episcopal towns often appeared through their representatives. By the 14th century, therefore, the originally homogeneous diet of princes was already in practice, if not yet in legal form, divided into three colleges—the electors, the princes and nobles and the representatives of the towns (though, as will be seen, the latter could hardly be reckoned

as regular members until the century of the Reformation. The power of the diet during the middle age extended to matters such as legislation, the decision upon military expeditions (especially the *expeditio Romana*) taxation and changes in the constitution of the principalities or the empire. The election of the king, which was originally regarded as one of the powers of the diet, had passed to the electors by the middle of the 13th century.

A new era in the history of the diet began with the Reformation. The division of the diet into three colleges was thereafter definite and clear. The representatives of the towns became regular members, but it was not until 1618 that they were recognized as equal to the other estates of the diet. The estates of the princes and counts, which stood midway between the electors and the towns, also remained, in the years that followed the Reformation, its final organization. The vote of the great princes ceased to be personal and began to be territorial. It was not the status of princely rank but the possession of a principality which was thereafter a title to membership. The position of the counts and other lords, who joined with the princes in forming the middle estate, was also finally fixed by the middle of the 17th century. While each of the princes enjoyed an individual vote, the counts and other lords were strung in groups, each of which voted as a whole, though the whole of its vote (*Kurkollegium*) counted only as equal to the vote of a single prince (*Virilstimme*).

There were six of these groups, but as the votes of the whole college of princes and counts (at any rate in the 18th century) numbered 100 they could exercise but little weight.

The last era in the history of the diet may be said to open with the treaty of Westphalia (1648). The treaty acknowledged that Germany was no longer a unitary state but a loose confederation of sovereign princes and the diet accordingly ceased to bear the character of a national assembly and became a mere congress of envoys. The last diet which issued a regular "recess" (*reichshausbuch*—the term applied to the acts of the diet, as formally compiled and enunciated at its dissolution) was that of Regensburg in 1654. The next diet, which met at Regensburg in 1663, never issued a recess and was never dissolved, it continued in permanent session, as it were, till the dissolution of the empire in 1806. This result was achieved by the process of turning the diet from an assembly of principals into a congress of envoys. The emperor was represented by two *commissarii*, the electors princes and towns were similarly represented by their accredited agents. In practice, the diet had nothing to do and its members occupied themselves in "wrangling about chairs"—that is to say, in unending disputes about rights of precedence.

In the Germanic confederation, which occupied the interval between the death of the Holy Roman empire and the formation of the North German confederation (1815-66), a diet (*bundestag*) existed which was modelled on the old diet of the 18th century. It was a standing congress of envoys at Frankfurt on Main. In the North German confederation (1867-70) a new departure was made, which was followed in the constitution of the German empire after 1870. Two bodies were instituted—a *bundesrat*, which resembled the old diet in being a congress of envoys sent by the different states of the confederation, and a *reichstag*, which bore the name of the old diet but differed entirely in composition. The new *reichstag* was a popular representative assembly, based on wide suffrage and elected by ballot, and, above all, it was an assembly representing not the several states, but the whole empire, which was divided for this purpose into electoral districts. Both as a popular assembly and as an assembly which represented the whole of a united Germany, the *reichstag* of modern Germany went back, one might almost say, beyond the diet even of the middle ages to the days of the old Teutonic folkmoet.

See R. Schröder, *Lehrbuch der deutschen Rechtsgeschichte* (1902), pp. 149, 508, 820, 880. Schröder gives a bibliography of monographs bearing on the history of the medieval diet. (E. B.)

DIET AND DIETETICS. Dietetics is the science and art of feeding human beings. It involves a knowledge of foods, their composition and preparation, and what they contribute in essential

nutrients for tissue repair and growth, for heat and energy and the normal functioning of the body.

Most if not all foods contribute more than one essential nutrient. Nutrients are chemical substances or compounds which make specific contributions to some phase of the body economy. Bread, milk, apples, oranges and carrots are examples of foods, while nutrients are such things as ascorbic acid (vitamin C), found abundantly in citrus fruits, calcium, found abundantly in milk, iron, found in fruits, vegetables, meat, enriched white bread and other foods, and proteins, found in varying amounts in milk, meat, eggs, fish, poultry, beans, nuts and, to a lesser extent, in cereals and other foods. By satisfying hunger with a reasonable variety of foods the normal individual is provided with essential nutrients in amounts sufficient to maintain the body in a state of health.

In any consideration of food needs it is essential to bear in mind the fact that wholesome foods all contain a variety of nutrients, each capable of contributing to body needs. In fact, it is characteristic of foods that they contribute more than one nutrient. Granulated sugar is often thought of as a food, but it is actually in isolated nutrient. It is a pure carbohydrate sucrose, which contributes calories only. On the other hand, white flour is often thought of as merely starch. In reality, it contributes a variety of nutrients. Whole wheat flour and white flour, enriched with nutrients known to be lost in milling, contribute a great variety of essential nutrients. Both of these make important contributions to the body's supply of needed protein, iron, thiamine and other B vitamins. The laudable practice of adding significant amounts of milk to bread (as much as 6% of nonfat milk solids may be added in the preparation of bread) permits this food to contribute to the body's need for calcium, and has improved the protein content of bread. Meats ordinarily thought of as protein foods furnish many other constituents. They supply varying amounts of fat in addition to B vitamins, iron and other minerals. Milk is often called man's most nearly perfect food because it supplies such a variety of nutrients. It contributes fats, carbohydrates, proteins, minerals and vitamins. Without milk in the diet it is difficult to meet the calcium needs of the body. Vegetables supply a great variety of minerals and vitamins when cooked properly or when eaten fresh. Green and yellow vegetables contribute importantly to vitamin A needs. Ripe fruits supply sugars as well as vitamins and minerals.

Basic Food Groups.—Most of our foods are included in the following five groups: (1) cereals and cereal products, (2) meat, eggs, poultry and fish, (3) milk and milk products, (4) fruits, and (5) vegetables.

For purposes of giving emphasis to certain foods these basic natural food groups may be subdivided still further. For example, milk and milk products is sometimes divided into two groups, one including butter and another including milk and the other milk products. Sometimes vitamin C rich foods are considered as a special group for emphasis. Such a group would include the citrus fruits, tomatoes, cantaloupes and strawberries.

These basic food groups furnish a guide to the preparation of an adequate diet without recourse to more profound scientific knowledge. More precise selections and greater variety may be obtained by taking advantage of technical information concerning nutrient values which are discussed later in this section.

Acceptable diets, containing all essential nutrients and capable of sustaining good nutrition, can be obtained when the daily diet includes foods from each of the five groups of foods mentioned above. By varying the selection of foods in each group, meals can be made interesting as well as fully nourishing. Furthermore, for variety or economic reasons it is often possible to supplement the foods of one group with those of another. The daily allowances indicated below are suggestive only, but they do indicate a simple manner of selecting an acceptable diet.

Basic Food Guide.—Whole Grain or Enriched Cereals and Breads.—Daily allowances for adults and children are three servings, for adolescents more is required, sometimes as much as six servings daily.

Meats, Fish, Poultry, Eggs—These include beef and lamb, mutton and lean pork, the organ meats, such as liver, heart, kidney, brains, sweetbreads, also fish, poultry eggs and game. Sources of vegetable protein which may be used as supplements or extenders are soybeans, dried beans, peanuts and nuts. Eggs and cheeses including cottage cheese are excellent sources of animal protein. Daily allowances about two servings daily for adults and school children, three for adolescents and one for preschool children. In pregnant and lactating women a liberal intake of protein foods is usually recommended.

Milk and Milk Products—These include whole skimmed, evaporated and dried milk, acidified milks and cheeses. Daily allowances for adults, two to three cups, for school children and preschool children, about three to four cups, for adolescents four cups.

Fruits—Daily allowance is two or three servings. In the selection of fruits it is essential to include fruits which are good sources of ascorbic acid (vitamin C), such as the citrus fruits, tomatoes, cantaloupes, strawberries and fresh pineapple. Many green vegetables are also good sources of vitamin C. The daily allowance of citrus or tomato juice is as follows for adults and school-age children, one half cup, for adolescents, three-fourths cup, and for preschool children one third cup—more if desired.

Other fruits include apples, apricots, avocados, bananas, cherries, currberries, cranberries, dates, figs, grapes, peaches, pears, persimmons, prunes, rhubarb and watermelon. Daily allowance, one or more servings for individuals of all ages.

Vegetables—Daily allowance of green or yellow vegetables for adolescents and school children is one half cup or more, for preschool children, one fourth cup or more. One or more servings of other vegetables should be included daily.

Exceptions to the rule that the five basic food groups will supply all nutrients known to be essential may occur in certain circumstances. Iodine is an essential nutrient, but it is lacking or present only in negligible amounts in the drinking water and food in parts of most continents. In Canada this lack has been remedied by making it mandatory for manufacturers of salt to add minute but specified amounts of iodine to all table salt. The lack of sufficient iodine to supply body needs is an important factor in the production of simple goitre (*q.v.*). The regular supply of traces of iodine in food or water appears to be an important weapon against this disease.

Vitamin D, important in tooth and bone development and in the prevention of rickets in babies, is not always present in the diet or otherwise available unless special precautions are taken. When not present in foods this lack can be remedied by sunbathing, but when this is not possible the deficiency may be remedied by adding vitamin D concentrate or the pure vitamin to the diet. Four hundred international units is generally regarded as an adequate daily intake. Infantile rickets has been greatly reduced by the widespread use of vitamin D preparations and by the use of vitamin D milk. (See also VITAMINS.)

Nutrients and Nutrient Needs in Diet Planning—Essential nutrients are supplied in the form of proteins, carbohydrates, fats, vitamins and minerals. All of them fall into these five general groups.

Proteins—G. J. Mulder, in 1838, gave us the name "protein," which has come to include a large group of related nitrogen-bearing organic compounds. The proteins are widely distributed in nature and no life is known without them. Man builds the proteins that he needs for growth and repair of tissues by breaking down into their component parts the proteins obtained in food, and by building up these components, the amino acids, into proteins of the type needed. Plants, on the other hand, build their proteins from the simpler inorganic materials found in the soil and air.

The dietary protein needs of man are supplied from both plant and animal sources. The protein rich foods from animal sources, such as milk, eggs, meat, fish and poultry, contain complete proteins. Complete proteins supply all the amino acids necessary in the human diet. The vegetable proteins vary in their biological value in that they supply varying amounts of the

essential amino acids. Combination of proteins of plant and animal origin work well together in supplying the protein needs. Of the vegetable proteins the chief sources are grain. Other sources include soybeans, peanuts, beans and nuts. Fruits and vegetables contribute little to the total protein requirement.

A protein allowance of one gram per kilogram of body weight per day for the normal adult is widely accepted as allowing a good margin of safety. (Special dietary needs for protein are discussed elsewhere in this section under the heading *Special Dietary Needs of Population Groups*.) The minimal requirement of protein is apparently in the neighbourhood of one half gram per kilogram of body weight per day.

Carbohydrates—The most abundant and least expensive food sources of heat and energy are the carbohydrates. There is a great variety of them. Important dietary carbohydrates are divided into two groups: starches and sugars. The starches may be converted into utilisable sugars in plants or in our bodies. Important sugar includes the monosaccharides, the disaccharide (common table sugar is in this group) and the polysaccharides. Starches are abundant in the grains and in potatoes, both of which are important staple items of most diets. Starches are present in vegetables in varying amounts. In fruits starches tend to be converted into sugars with ripening. Most of the starch in a banana, for example, has been changed to sugar by the time it is fully ripe.

Actually, the caloric need of an individual (supplied by fats and proteins in addition to carbohydrates) is that amount of energy food which will maintain body weight over a prolonged period at an optimal level, in the case of a growing child the caloric need is the amount that will maintain a satisfactory rate of growth. (Caloric needs are also discussed under the section *Special Dietary Needs of Population Groups*.)

Fats—The fats are widely distributed in nature and are a concentrated food source of heat and energy. Some fat is apparently essential in the diet although the precise mechanism of the role of essential fatty acids requires further study. Fats are glycerol esters of fatty acids. When broken down by hydrolysis fats yield fatty acids and glycerine. After digestion and absorption fats are used as sources of heat and energy or they may be stored in the fat deposits of the body. Body fat can be produced from the carbohydrate taken in the diet and may be stored likewise as fat deposits when more is taken than is needed. The ordinary diet containing milk and meat usually contains a full quota of fat.

The vitamins—The vitamin needs of the body with the possible exception of vitamin D in infancy and childhood, are supplied in quantities sufficient to meet dietary requirements in the foods which comprise an acceptable wholesome diet. These substances are required only in minute amounts daily, often in amounts so small it is to be invisible to the naked eye. Basic requirements for some are reasonably well established, but like most essential nutrients nature tends to supply more than is needed for basic body needs in health. Lack of individual vitamins produces characteristic deficiency states and the overuse of some of them has been shown to have harmful effects. It is desirable, therefore, that the intake should be adequate but not excessive. When vitamins are taken in the form of foods the likelihood of excessive use is remote. The therapeutic use of chemically pure vitamins in excess of normal needs is not within the purview of this report. The recommended daily dietary allowances as reported by the Food and Nutrition Board of the National Research Council will be found in their bulletin on dietary allowances (see *Bibliography*) for the following vitamins: vitamins A and D, thiamine, riboflavin, niacin and ascorbic acid. In the case of a physically active man weighing 70 kg (154 lb.) the following daily allowances are recommended: vitamin A, 5,000 international units, thiamine, 1.5 mg, riboflavin, 1.8 mg, niacin, 15.0 mg, ascorbic acid, 75.0 mg. In cases of special stress, as in adolescence and in pregnancy and lactation, slight to moderate increases are recommended.

Vitamin A is found abundantly in green and yellow vegetables, in eggs and milk and butter. Thiamine (vitamin B₁) is widely

distributed in nature. It occurs in fruits and vegetables. In grains it is most abundant in the embryo or germ portion of the kernel. With other vitamins of the B complex it is found in meat. Milk and milk products, lean meat and leafy vegetables are all good sources of riboflavin. The food sources of niacin and compounds which favour the production of niacin are widespread and apparently entirely adequate in any acceptable diet. Niacin is found in meat, whole grain and enriched cereals. The relation of tryptophane to niacin has been pointed out by C. A. Elvehjem. This accounts for the antipellagra effect of milk. Ascorbic acid is widely distributed in the fruits and vegetables but it is rather easily affected by heat hence the importance of including such foods as fresh citrus juices, tomatoes and strawberries in the diet. Vitamin D is not widely distributed in foods but for normal adults who work out of doors there seems to be little need for supplementary doses. The diets of infants and children and some others need to be supplemented with concentrates or the pure vitamin.

Minerals—Of the many minerals that are eaten with foods, calcium and iron have received much attention. Besides these there are many others which are required, often in ways that are less well understood. Calcium is needed in bone and tooth growth and repair. At present the recommended dietary allowance for calcium is one milligram daily, but its minimal requirement is less. A most abundant food source of calcium is milk. Other foods supplement this source but less abundantly. Iron is supplied in meats and in fruits, vegetables and cereals. It is widely distributed and is needed in the formation of the blood haemoglobin.

Special Dietary Needs of Population Groups—Infants—Infants are best fed on their mothers' milk. But mother's milk alone does not necessarily ensure good growth and development of the baby. Harold C. Stuart of Boston, Mass., and Fred Tisdall of Toronto, Can., and their associates demonstrated for him in beings a fact long known to the animal husbandrymen *who raise fine animals*. These physicians showed that an adequate diet and good hygiene during pregnancy are essential to the well-being of both mother and baby. The mother cannot supply a full quota of essential nutrients to her unborn child unless she herself has an adequate supply of the basic food nutrients, nor can she do so after it is born. The first principle of successful breast feeding is to see to it that the mother is in the best possible health and receives an ample basic diet during pregnancy and during the period of lactation.

Infants need food for growth in addition to their other body needs. On the basis of weight they require about four times as much protein as an adult. When the mother's milk is not available cow's milk, goat's milk or special soybean milk are acceptable substitutes. Extra calories for heat and energy are often needed and are supplied by adding sugars (maltose dextrin mixtures, lactose, dextrose, sucrose, etc.) to the baby's formula. In order to assure an ample supply of vitamin C, orange juice is started at an early age, often it is added at the end of the second week, in small quantities at first, later increasing. In order to provide an adequate vitamin D intake for the prevention of rickets and the normal growth of bones, 400 international units of vitamin D are added each day. As the baby grows older cereals are added to supply extra calories as well as minerals and vitamins. Strained fruits and vegetables supplement the supply of vitamins and minerals and are often started at about the fourth month. Strained or scraped meat may be added at about the same time as other solid foods are started. Meats supply protein, minerals and vitamins, particularly the B vitamins. When the baby is able to chew, foods of coarser texture are substituted.

Of particular importance in the feeding of babies is strict cleanliness. Foods, particularly milk, provide excellent mediums for the growth of bacteria. Milk should be sterilized or pasteurized before feeding. Clean uncontaminated foods of good nutritive quality have contributed importantly to the reduction of infant mortality.

Older Children—As children grow their need for more food

becomes apparent. Healthy children need never be forced to eat. In fact, it is a good rule never to force a child to eat. If an adequate supply of wholesome foods is placed before him hunger will cause him to eat adequately.

The Adolescent—During adolescence there is a period of rapid growth and adjustment, both physically and psychologically. The need for food is increased even above that of the average adult. Adolescents need and demand more of almost all of the foods.

Men—The nutrient needs of adult males are essentially the same as those of any other individual except that the total amount of food required varies depending upon the type of work that the man is called upon to do. The total number of calories and the total amount of food varies both with the amount of muscle work involved and with the temperature of the environment. For example, the adult male of average size in a sedentary occupation requires about 2,400 cal daily, but if he is called upon to do very heavy manual labour the (illicit) requirement may be nearly doubled. Observations on soldiers in the arctic indicate that an additional amount of food is required because of excessive cold.

Women—The dietary needs of women differ apparently from those of men principally, or perhaps simply, in degree. An average woman who weighs 55 kg, or about 123 lb, and who is relatively inactive requires in the neighbourhood of 2,000 cal daily. If she is very active she may require about one third more.

Pregnancy and Lactation—During pregnancy and lactation women require a moderate increase in calories and a definite increase in the protein content of their diet as well as in the vitamin and mineral content. For example the recommended allowance of calcium is from 50% to 100% greater and the iron requirement is slightly increased, as are the requirements of most of the vitamins. Diet directions for pregnant and lactating women have been worked out in considerable detail and checked with carefully controlled observations by Bertha Burke and Harold C. Stuart of the Harvard university school of public health, Boston, Mass.

The Aged—The food needs of the aged require a great deal more study than has been given to the subject thus far. Apparently the food needs of individuals in this group are similar to those of younger persons, although lack of teeth or other such handicaps may require special attention to the form in which food is supplied. It is probable, too, that sedentary individuals in this group require less food than active persons for the same reasons that inactive younger persons need less than active.

Dietary Needs in Illness—Such rapid progress is being made in this area of scientific endeavour that it is scarcely worth while to record advances here because they are so rapidly supplemented and enlarged upon as a result of new researches. A few examples of advances in the dietary management of disease will suffice. Specific deficiency diseases resulting from deficient intake of individual nutrients or groups of nutrients are treated by supplying an adequate diet with supplements of the individual nutrients previously lacking. Rickets, now almost unknown in the United States, Canada and England, is treated by supplying vitamin D in adequate amounts. Scurvy is treated by supplying an adequate diet plus large doses of vitamin C in the form of the pure vitamin or in the form of fruit juices naturally rich in this vitamin. Pellagra and beriberi are other deficiency diseases requiring specific treatment. Special dietary treatment of patients suffering from extensive superficial burns involves a supply of two or three times the normal requirement of protein. This is given both intravenously and by mouth and resulted in the saving of many lives during World War II. Acute infectious hepatitis, a disease associated with an enlarged, tender liver and yellow skin, has been shown to respond quite dramatically to a supplemented protein intake. Thanks to the epoch-making discovery of G. R. Minot and W. Murphy, pernicious anaemia, once a regularly fatal disease, may now be successfully treated with liver or liver extract. The discovery of vitamin B₁₂ helped to simplify treatment.

The Quality of Foods—What are some of the criteria by which the quality of foods is evaluated? First and foremost, a food must make a significant contribution to the human dietary requirements. Ideally, the food should make the expected contribution of the best specimens in its particular group. Efforts are constantly made to improve foods through the selection of better varieties of plants and breeds of animals. Most fruits and vegetables are richest in nutritive values when freshly picked. Unless refrigerated or otherwise properly stored they deteriorate with standing. Cool or cold storage temperatures are important considerations. Nutrient losses tend to be accelerated by high storage temperatures. Cold storage and the development of quick freezing techniques have done much to conserve nutrient quality.

Foods must be clean. Surfaces must be clean or capable of being cleaned by washing or scouring or removal of the surface layers. Foods must be free from insect parts, rodent hairs or excreta or other filth. These are usually things that the ordinary consumer cannot recognize. For protection he must depend upon the technical ability and vigilance of food handlers and government experts.

Foods must be free from harmful bacteria. Milk, particularly, is likely to be the carrier of harmful organisms unless especially protected through care in handling and pasteurization. Infected milk is known to have been the carrier of tuberculous typhoid fever, septic sore throat and other infectious diseases. Advances have been made in the quality of cheese. Certain communities require that all cheese either be made from pasteurized milk or aged for a sufficient length of time to ensure that harmful bacteria have been rendered innocuous. In certain parts of the world where the soil is contaminated with the eggs of intestinal parasites an important criterion of quality is freedom from these contaminations. In such areas it is usually necessary, however, to scrub, wash, peel or cook vegetables and fruits carefully in order to ensure their safety.

Wholesome foods are free from the presence of chemical contaminants. Chemical contamination of foods may occur either by accident or by intent. During and after World War II large numbers of pesticides (poisons developed for the control of insects and other pests) were developed. The health hazards of pesticide residues on foods brought about intensive research on this problem and active steps were taken to establish safe methods of use. Many chemicals are proposed each year for use in foods for the purpose of improving their colour, texture and appearance. Some of these are harmless, others are not. A wholesome food must contain no added chemicals unless they have been proved beyond reasonable doubt to be harmless; the chemicals must not be employed to conceal evidence of inferior quality. A number of chemicals and hormones have been used experimentally in animals for the purpose of improving milk production or the quality of meat. Milk or meat produced from such animals must be regarded as of questionable quality unless the substances used can be demonstrated to be harmless when consumed with the milk or meat.

The Preservation of Foods—New ways of preserving food are being developed and old techniques improved constantly. One of the oldest methods is dehydration. Preservation with spices, pickling fluids and salt and by cooking and the use of cold were originally introduced long ago. Refinements of some of these methods were developed by mid 20th century; one of special interest being the quick freezing technique. Quick freezing, of course, does not improve the quality of foods. It simply is a good method of conserving the original nutrients of the food at the time when the process was started. The quality of frozen foods depends to a large extent upon the quality of the foods put into the freezer. This fact is true of other techniques but is often overlooked.

Cooking—One of the chief reasons for cooking many foods lies in the fact that it makes them more palatable and easier to eat, and sometimes easier to digest. For example, long, slow cooking will often make a tough piece of meat tender. Cooking improves the digestibility of certain classes of foods. It splits the

envelopes of starchy granules, it favourably affects milk curds so that they are smaller and softer when they reach the stomach and thus more readily digested. Cooking kills micro organisms and the eggs of parasites. Raw or smoked pork for example should never be eaten, it should always be cooked in order to kill the parasite which produces trichinosis. Cooking reduces or destroys some of the vitamins especially those which are readily affected by heat: Vitamin C, or ascorbic acid, is one of the nutrients which is readily destroyed by heat in the presence of oxygen. This is one of the reasons why fresh fruit and garden vegetables in salads are useful additions to the diet. Generally speaking, when vegetables are cooked they should be subjected to heat for the shortest time possible, to accomplish the desired results. A minimum of cooking water should be used. When the cooking water is thrown away valuable nutrients usually go with it. **Minimal Daily Requirements of Nutrients**—The smallest amount of an individual nutrient that will sustain normal nutrition is said to be the minimal requirement of the nutrient in question. These minimal requirements vary with age, with the amount of food taken and for other reasons. In actual practice nature has provided when a diet of wholesome foods is ingested, that nutrients shall be present in slight to moderate excess of the basic or minimal requirement. Thus, in actual practice and in the calculation of diets, the dietitian and nutritionist usually estimate food nutrient requirements sufficiently above the level requirement to permit a reasonable margin of safety. One of the important contributions of the Food and Nutrition Board of the National Research Council has been the preparation of a report called *Recommended Dietary Allowances*. This report has had important effects on the thinking and practice of most dietitians and nutritionists.

DIETARY see DIET and DIETETICS
DIETERICH, FRIEDRICH (1821-1903), German orientalist and a pioneer in mediaeval Arabic studies, was born on July 6 1821 in Berlin where he died on Aug. 18, 1903. He travelled in Egypt and the near east from 1847-49, and on his return became professor at Berlin. His writings did much to stimulate an appreciation of the speculations of the mediaeval Arabs, they include *Alfihk al-carmen grammaticum auctore Ibn Malik* (1851), *Mutanabbi carmina cum commentario Wihidi* (1858), *Die Philosophie der Ibrer im 9. u. 10. Jhr n. Chr.* (1876-94), *Die soeconomic Theologie des Aristoteles*, trans. from Arabic (1883), *Der Streit zwischen Mensch u. Thier* aus den Schriften der lauterer Bruder ubersetzt (1858), *Alfarabi philosophische Abhandlungen*, Arabic ed. (1892), *Der Musterstaat von Alfarabi* trans. from Arabic (1900), *Christomathe Ottomane* (1854), and an oriental novel, *Mirjam* (1886).

DIETHER VON ISENBURG (1412-1461), second son of Count Diether of Isenburg-Budingen, was rector of the University of Erfurt in 1434 and became archbishop of Mainz in 1450. He led the movement for the reform of the empire, and the opposition to the papal encroachments, supporting the theory of church government enunciated at the councils of Basel and Constance and condemned in Pius II's bull, *Fecit nobis*. (See PARACLY.)

DIETRICH, CHRISTIAN WILHELM ERNST (1712-1774), German painter and engraver, was born at Weimar on Oct. 25, 1712, and died at Dresden on April 24, 1774. He was taught by his father, Johann George, painter of miniatures to the court, and was then sent to Dresden to work under Alexander Thiele the landscape painter. Augustus II, King of Saxony sent him to Italy and the Netherlands where he learned to imitate the masters of the previous century with amazing fidelity. At Dresden there are pictures acknowledged to be his, bearing the fictitious dates of 1636 and 1638 and the name of Rembrandt. His "Itinerant Musicians," in the manner of Ostade, is in the National gallery, London. In 1741 he was appointed court painter to Augustus III at Dresden, with an annual salary conditional on the production of

four pictures a year and there are 5. of his canvases and panels in one room at the Dresden museum. A collection of his engravings at the British museum produced on the lines of earlier men, such as Ostade and Rembrandt reveal both spirit and skill. Dietrich after his return from Italy generally signed himself 'Dieterich'. He was director of printing at the Meissen porcelain factory and professor at the Dresden academy of arts.

DIETRICH OF BERNE, name given in popular story to Theodoric the Great. The legend differs so widely from the true history that even in medieval times some doubted the connection and noted the glaring anachronisms. But the identity seems to be proved by the names Dietrich (Theodoric), Dietmar (Theudemir) Berne (Verona), Raben (Ravenna), and there is some resemblance in character between Theodoric and Dietrich. The south German cycle of Dietrich songs is partially preserved in the *Hildebuch* (q.v.), *Dieterichs Flucht*, the *Rabenschlacht* and *Alpharts Tod*, but it was reserved for a 13th century Icelandic to compile a consecutive account. This prose reduction (*Vikina* or *Thidreksaga*) incorporates much matter from the Nibelungen and Wayland legends, in fact, nearly the whole south German epos.

There are traces of a form of the story in which the hero started out from Byzantium for the conquest of Italy. But this was very early superseded by the existing legend, in which, perhaps by epic fusion with his father Theudemir, he was associated first with Attila and then with Ermanaric, by whom he was driven from his kingdom of Berne. After years of exile at Attila's court he returned with a Hunnish army and defeated Ermanaric in the Rabenschlacht (battle of Ravenna). Attila's two sons fell in the fight, and Dietrich returned to Attila to answer for their death; this seems to suggest that originally the Rabenschlacht was a defeat. In *Ermenrichs Tod* he slays Ermanaric, as in fact Theodoric slew Odovacer, in the *Hildebrandslied* "Otacher" takes the place of Ermanaric. Dietrich's long stay with Attila represents Theodoric's youth spent at the Byzantine court. The period of exile was as usual adorned with marvellous exploits, most of which had no connection with the cycle, the poems of *König Laurin*, *Sigenot*, *Eckenste* and *Virginal* are based largely on independent traditions. Through Attila, Dietrich enters the Nibelung cycle. In the final catastrophe it is he who, to avenge his Amelungs, at last delivers Hagen to Kriemhild. His "flame breath" seems to be pure myth, but the tales of his demonic origin and of his being carried off by the devil may be ascribed to clerical hostility to Theodoric's Ananism.

Dietrich typifies the wise and just ruler as opposed to Ermanaric the typical tyrant. He is invariably represented as slow to anger, but once roused he overcomes even Siegfried (but probably the fight in the rose garden at Worms is a late accretion). The chief heroes of the Dietrich cycle are his tutor and comrade Hildebrand (see *HILDEBRAND, LAY OF*), with his nephews the Wolfings Alphart and Wolfhart, Wutich, who renounced his allegiance and slew Attila's sons, and Heme and Biterolf.

BIBLIOGRAPHY—The poems of the Dietrich cycle are summarized by L. Uhland, *Schiffen zur Geschichte der Dichtung und Sage* (Stuttgart, 1866-72). *Thidreksaga* ed. by Unger (Christiana, 1853), is translated into German by Von der Hagen, *Altdeutsche Heldensagen* (3rd ed., Breslau, 1872). A summary of the legend is in T. Hodgkin, *Theodoric the Goth* (1891). Part of *Thidreksaga* is in T. Mohr, *Analekten Norroena* (Leipzig, 1877). See also W. Grimm, *Deutsche Heldensagen* (1867), accounts in Sandbach, *Saga Cycle of Dietrich* (1906), O. J. Irizcek, *Die deutsche Heldensage*, trans. by Bentock-Smith, *Northern Legends* (1902). Original extracts, Irizcek, *Kundun und Dietrichsagen* (Stuttgart, 1895). For full bibliography, see Symons, *Deutsche Heldensagen*, in H. Paul, *Grundriss der germanischen Philologie* (1899-91), also K. Goedeke, *Grundriss zur Geschichte der deutschen Dichtung* (1857-81).

DIEZ, FRIEDRICH CHRISTIAN (1794-1876), German philologist, the founder of Romance philology, was born at Gießen, Hesse-Darmstadt, on March 15, 1794. A visit to Johann von Goethe in 1818 decided the direction to his studies. Goethe had been reading François Raynaud's *Chans de poésies originales des troubadours*, and advised the young scholar to explore the rich mine of Provençal literature which the French savant had opened up. Henceforth Diez devoted himself to Romance literature. He

moved in 1822 to Bonn, where he held the position of *Privat docent*. His *Poésie der Troubadours* (1846) and *Liben und Werke der Troubadours* (1859), of both of which there are modern editions edited by Karl Bartsch, were his earliest important studies. In 1830 he became professor of modern literature at Bonn. The rest of his life was mainly occupied with the composition of the two great works on which his fame rests, the *Grammatik der romanischen Sprachen* (3 vol., Bonn, 1836-44, 5th ed., 1882) and the *Etymologisches Wörterbuch der romanischen Sprachen* (2 vol., Bonn, 1853, 5th ed., 1887), in these two works Diez did for the Romance group of languages what Jacob Grimm did for the Teutonic family. He died at Bonn on May 29, 1876. He also wrote works on Spanish and Portuguese language and early literature.

See W. Foerster, *Friedrich Diez* (1894).

DIEZ, town of Hesse Nassau, Ger., in the deep valley of the Lahn, crossed by an old bridge, 30 mi E from Coblenz on the railway to Wetzlar. Population 3,850. It is overlooked by a former castle of the counts of Nassau Dillenburg, now a prison. Close by, on an eminence above the river, lies the castle of Oranienstein, formerly a Benedictine nunnery. The industries include iron works, machine making, colour preparation, lime burning and quarrying. In the vicinity are Fachingen, celebrated for its mineral waters, and the castle of Schaumburg.

DIFFERENTIAL, in a motor car (q.v.), the system of gears (usually situated in the back axle) by means of which one driving wheel may revolve with increased speed while the other is checked (in taking corners, etc.). In physics, differential apparatus (e.g., a differential thermometer) is designed in such a manner that errors caused by extraneous effects in the experiments are eliminated. (See THERMOMETRY.)

DIFFERENTIAL CALCULUS, ABSOLUTE see TENSOR ANALYSIS.

DIFFERENTIAL EQUATIONS. In any scientific or technological field, such as astronomy, chemistry, engineering, physics, etc., the formulation of a natural law is regarded as completely precise and definitive only when it is expressed as a mathematical equation. This equation effectively relates the quantity, or function, upon which the attention is focused, with the independent variables such as time, position, etc., upon which it may depend. Now it is frequently—even prevalently—the case that the equation which does this involves besides the function itself, also one or more of its derivatives. Such an equation, specifically one in which a derivative or derivatives occur, is called a differential equation. The following are examples of such equations

$$\frac{dy}{dt} = -ky, \quad (1)$$

$$m \frac{d^2y}{dt^2} = -k^2y, \quad (2)$$

$$\left\{ 1 + \left(\frac{dy}{dx} \right)^2 \right\} \frac{d^2y}{dx^2} - 3 \frac{dy}{dx} \left(\frac{d^2y}{dx^2} \right)^2 = 0 \quad (3)$$

In these y stands for the function, and either t or x is the independent variable. The symbols k and m are used here to stand for specific constants.

Classifications—Differential equations are classified in the first instance into several broad categories, and these are in turn subdivided into many subcategories. Of the former the most important are (a) the category of the so called ordinary differential equations and (b) that of the so called partial differential equations. When the function involved in the equation depends upon only a single variable its derivatives are ordinary derivatives, and the differential equation is classed as an ordinary differential equation. If, on the other hand, the function depends upon several independent variables, so that its derivatives are partial derivatives, then the differential equation is classed as a partial differential equation.

Whenever the type may be, a differential equation is said to be of the n th order if it involves a derivative of the n th order but no derivative of an order higher than this. The differential equations (1), (2) and (3) are all ordinary differential equations

They are, respectively, of the first, second and third orders. The equation

$$\frac{d^3u}{dt^3} = k \left[\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} \right], \quad (1)$$

is an example of a partial differential equation. It is of the second order. The theories of ordinary and partial differential equations are markedly different. In almost all respects the former is the simpler.

2 Some Examples of the Formulation of Natural Laws

—The way in which differential equations are utilized for the expression of natural laws is indicated in some small measure by the following examples.

A certain lot of radioactive chemical is constantly disintegrating, the rate of this process being at each instant proportional to the amount of the material which is then left. If the chemical is designated by y , and t is taken to stand for the time, the rate of the disintegration is $-dy/dt$. The stated law asserts that this value is always proportional to y , namely, that it is always equal to ky with k an appropriate constant. The law is, therefore, expressed by the differential equation (1) above.

If a heavy particle is suspended from a coiled spring, the position in which it will hang in a continued state of rest is called its position of equilibrium. On a vertical y axis this position can be taken as the point $y=0$. If the particle is vertically displaced from this position it will be subject to a restoring force that is always proportional to its co-ordinate of position y , and is opposite to this in sign. The formula for this force is, therefore, $-ky$ with an appropriate constant k . By Newton's second law of motion, the product of the mass m of the particle by its acceleration d^2y/dt^2 , is equal to the force. The law of motion in accordance with which the particle oscillates up and down is, therefore, expressed by the differential equation (2) above.

It is shown in the calculus that the curvature K of a curve $y=f(x)$ is given by the formula

$$K = \left[1 + \left(\frac{dy}{dx} \right)^2 \right]^{-3/2} \frac{d^2y}{dx^2}$$

The fact that a certain curve is a circular arc, may, therefore, be brought to expression by the assertion that along it K does not change, namely, by the equation $dK/dx=0$. This is found to be given explicitly by the differential equation (3) above. That equation thus formulates mathematically the law of the circular nature of the given arc.

Further illustrations of this process of the translation of scientific laws into differential equations will be found in practically all text books on the subject. The references given in the bibliography at the end of this article, numbered (3), (5), (9), (12) and (15), are typical in this respect.

3 Solutions of Differential Equations—An ordinary differential equation in which, for example, the function and the independent variable are denoted by y and x , is in effect an implicit summary of the essential characteristics of y as a function of x . These characteristics would presumably be more accessible to analysis if an explicit formula for y could be produced. Such a formula, or at least an equation in x and y (involving no derivatives), which is deducible from the differential equation is called a solution of the differential equation. The process of deducing a solution from the equation by the applications of algebra and the calculus is called that of solving or integrating the equation. Some methods that serve for the integration of certain classes of differential equations will be explained below. In the broader sense, however, it must be said that the differential equations which can be integrated form but a small minority. The chances are large, in the instance of a differential equation selected at random, that the equation is itself the simplest mode of summarizing the characteristics of the function, and that even theoretically no solving formula in the usual sense exists. The function must in such instances be studied by indirect methods. Even its existence must be proved when no possibility of producing it for inspection maintains. These subjects find their place in the more advanced theory (cf. references (2), (7) and (8)).

4 Quadratures—An ordinary differential equation which is of so simple a type that their integration depends only upon an obvious application of the calculus, let us consider the equations of the form

$$\frac{dy}{dx} = f(x), \quad (5)$$

in which $f(x)$ is a given function. The solution of this equation, namely

$$y = \int f(x) dx + c, \quad (6)$$

affords us the occasion for some remarks which are of rather general applicability. In the relation (6) the indicated integration calls for some (any) indefinite integral of the function $f(x)$. For many types of functions such integrals are to be found in "tables of integral," such as that given below by the reference (11). Not all functions $f(x)$, however, and not even all simple ones, have integrals that can be expressed by elementary closed formulas. Hence an indicated integration is not always replaceable by an expression that is more explicit. For this reason a relation in the form (6) is generally regarded as a satisfactory solution of the equation (5), just as it stands. The term quadrature is frequently used in the place of indefinite integral, the relation (6) being styled as a solution in terms of an indicated quadrature.

5 The General Solution—The final term of the relation (6), being a constant of integration, and hence being eligible to any value whatever, is called an arbitrary constant. For each specific value of this constant the equation (6) defines a curve in the (x, y) plane, and while the constant remains arbitrary the equation refers to the whole aggregate or family of these curves. This family is the solution of the differential equation. What is thus observed in the simple case of the equation (5) is generally true of differential equations. The process of solution draws one or more arbitrary constants into the relations, and these as a result represent a family of curves. A solution which includes the maximum possible number of arbitrary constants is called the general solution of the differential equation. It can be shown that this maximum number is precisely equal to the order of the differential equation, namely that the general solution of an ordinary differential equation of the n th order involves n arbitrary constants.

For any set of specific values of the constants the solving relation still yields a solution. Such a one is called a particular solution. In an obvious sense the general solution includes all the particular solutions. In the case of some differential equations still other solutions exist. These are called singular solutions. Discussions of this may be found in the references (5), (8), (9) and (12).

6 Initial and Boundary Conditions—The presence of arbitrary constants in the general solutions of ordinary differential equations is a matter of fundamental significance for the application of these equations to scientific problems, for such problems ordinarily call not merely for a solution of the equation, but for the solution which fulfills also certain other relations that are pertinent to it. These auxiliary conditions must, therefore, be fulfilled by the appropriate assignment of values to the arbitrary constants. Some examples will illustrate this.

In §2 it was shown how the disintegration of a chemical substance is formulated by the differential equation (1). The general solution of this equation is

$$y = ce^{-kt}, \quad (9)$$

in which the constant c is arbitrary. Now in any specific case the chemical is of a definite amount, say 20 grams, at some definite time, say at $t=2$. These values, upon being substituted for y and t in the equation, impose upon c the relation $20 = ce^{-2k}$, in accordance with which $c = 20e^{2k}$. The solution which fits this case is, therefore, $y = 20e^{k(2-t)}$.

It was also shown in §2 how the motion of a suspended particle is formulated by the differential equation (2). The general solution of this equation (obtained by a method described below) is

$$y = c_1 \cos \frac{kt}{\sqrt{m}} + c_2 \sin \frac{kt}{\sqrt{m}} \quad (10)$$

Now in any specific case the particle is at a definite place, say at $y=1$, and is moving with a definite velocity, say $dy/dt = -1$, at a definite time, say at $t=0$. These values, substituted into (10) and the derived equation impose upon c_1 and c_2 the relations $1=c_1$, and $-1=c_2 k/\sqrt{m}$. Thus it is requisite that $c_1=1$, $c_2=-\sqrt{m}/2k$, and accordingly the solution that fits the problem is

$$y = \cos \frac{kt}{\sqrt{m}} - \frac{\sqrt{m}}{2k} \sin \frac{kt}{\sqrt{m}}$$

Auxiliary conditions that are imposed upon the solution of a differential equation at some one value of the independent variable, as in the examples above, are called initial conditions. If the auxiliary conditions apply at two or more values of the independent variable, they are more usually called boundary conditions. Problems leading to such conditions are called differential boundary problems. The references (3) and (4) are primarily concerned with such problems. Considerable numbers of elementary initial value problems are to be found in the references (5), (9), (12) and (15).

DIFFERENTIAL EQUATIONS OF THE FIRST ORDER

Some Elementary Types

7 Equations with Separable Variables—The ordinary differential equation of the first order, when it is solved for the derivative is of the form

$$\frac{dy}{dx} = f(v, y), \quad (11)$$

in which $f(v, y)$ is an explicit function. A form which is obviously equivalent to this but which is in some respects more convenient, is

$$M(v, y)dv + N(v, y)dy = 0 \quad (12)$$

The case to which attention is to be given first is that in which the equation (12) is of the more special form

$$P(v)dv + Q(y)dy = 0, \quad (13)$$

or in which it can be brought into this form by multiplying it through by appropriate factors that are functions of x or of y . The salient specialization which distinguishes (13) from the general form (12) is that P , the coefficient of dv , does not involve y , and Q , the coefficient of dy , does not involve x . In the equation (13) the variables are said to be separated, and a differential equation which can be reduced to such a form is classified as an equation with separable variables. When the variables have been separated the integration of the differential equation devolves into a mere matter of quadrature. Thus the general solution of the differential equation (13) is given by the relation

$$\int P(v)dv + \int Q(y)dy = c, \quad (14)$$

with c denoting the arbitrary constant.

By way of example consider the differential equation

$$dy + ky \, dt = 0$$

This will be recognized as the equation (1) above. In this equation the variables are separable, for upon multiplication by the factor $1/y$ the form is changed to

$$\frac{1}{y} dy + k \, dt = 0,$$

in which the variables are separated. The integration now yields the solution

$$\log y + kt = c$$

The differential equation

$$y^2 dx + (4y-3) \cos^2 y \, dy = 0,$$

if multiplied through by the factors y^{-4} and $\sec^2 y$ takes the form

$$\sec^2 y \, dx + \left(\frac{4}{y} - 3\right) \frac{1}{y^2} dy = 0,$$

in which the variables are separated. The integration of it

yields the solution

$$\tan v - \frac{2}{y^3} + \frac{1}{y^2} = c$$

The differential equations

$$1 + 5\frac{dy}{dx} = 3 + v\frac{dy}{dx},$$

$$y^2 dx + \sqrt{v^2 - x^2} \, dy = 4dx,$$

are of this type. Their solutions are respectively

$$\log(v-5) - \frac{1}{2} \log(3^2-5) = c,$$

$$4 \sin v + \log \left(\frac{v-x}{y+2} \right) = c$$

8 Exact Equations—It is shown in the calculus that if two functions $M(v, y)$, $N(v, y)$, fulfill the relation

$$\frac{\partial M}{\partial y}(v, y) = \frac{\partial N}{\partial v}(v, y) \quad (15)$$

then there exists a function $\phi(v, y)$ concerning which it is true that $\partial \phi(v, y)/\partial v = M(v, y)$, and $\partial \phi(v, y)/\partial y = N(v, y)$. In accordance with this it is clear that if the differential equation (12) is one whose coefficients fulfill the identity (15) then the equation permits of being written in the form

$$\frac{\partial \phi(v, y)}{\partial v} dv + \frac{\partial \phi(v, y)}{\partial y} dy = 0$$

This may, however, be more concisely written as $d\phi = 0$, and thus it must be concluded that $\phi(v, y) = c$. This is, then, the general solution of the given equation. It remains only to describe the means by which the function $\phi(v, y)$ may be found. This may be done as follows: treating y as though it were a constant, evaluate the integral $\int M(v, y) dv$. Then treating x as though it were a constant, evaluate the integral $\int N(x, y) dy$. The sum of all unlike terms in these two evaluations (i.e. including no repetitions) is the function $\phi(v, y)$.

As an example consider the differential equation

$$(\cos y - y + 1) dx + (3y^2 - v \sin y - v) dy = 0$$

The two members of the identity (15) are in this case each $(-\sin y - 1)$, and thus the equation is exact. Regarding y as a constant, the first member of the equation integrates into $v \cos y - vy + 1$. Regarding v as a constant, the second member integrates into $y^3 + x \cos y - xy$. Setting the sum of unlike terms equal to an arbitrary constant gives as the general solution

$$v \cos y - 2y + 1 + y^3 = c$$

The differential equations

$$y(e^{xy} - \sin x) dv + (\cos v + xe^{xy}) dy = 0,$$

$$(2x^2 y^3 - 3) dx + (x^3 y + 8y - \frac{1}{y}) dy = 0,$$

may be verified to be exact. Their solutions are respectively

$$y \cos v + e^{xy} = c,$$

$$x^2 y^3 - 3x + 4y^2 - \log y = c$$

9 Integrating Factors—Although a differential equation, in the form in which it is come upon, may not be exact, it is possible to prove that by the multiplication with a suitable factor it may be made exact. Thus the differential equation

$$\left(xy + \frac{1}{xy} \right) dx + \left(1 - \frac{1}{y^2} \right) dy = 0, \quad (16)$$

is not exact, but if it is multiplied through by the factor x it becomes so. A multiplier, such as x in this instance, which makes a differential equation exact is called an integrating factor. Other integrating factors for the equation (16) are $y/(xy^2+1)$, and $x^2(xy+\frac{1}{y})$. It can be proved that for every differential equation of the form (12) an unlimited number of integrating factors exists. In some simple cases it is possible to guess an integrating factor. Many text books point out errors made to be sought in the differential equation as guides to such guessing. In actual

practice, however, integrating factors are usually not easily found

10 **The Linear Equation**—A differential equation which can be written in the form

$$\frac{dy}{dx} + Py = Q, \quad (17)$$

in which the coefficients P and Q may be constants or functions of x , but do not involve y , is called a linear differential equation of the first order. This is a type of equation which is of considerable importance in many different connections. When the equation is given the alternative form

$$[yP(x) - Q(x)]dx + dy = 0,$$

the remarks of §9 apply to it, and it is, in fact, found that the multiplier $e^{\int P(x)dx}$ is an integrating factor. By the method of §8 the general solution of the equation is thus found to be

$$ye^{\int P(x)dx} - \int Q(x)e^{\int P(x)dx} dx = C \quad (18)$$

As an example consider the differential equation

$$\frac{dy}{dx} + \left(1 + \frac{1}{x}\right)y = \frac{5}{x}$$

The integrating factor is $e^{x+\log x}$, a function which is more briefly written xe^x , and the solution of the equation is

$$xye^x - 5e^x = C$$

The differential equations

$$\frac{dy}{dx} + 2y \tan x = 2x \cos^2 x$$

$$(xe^{2x} - 2y\sqrt{1+x^2})dx + \sqrt{1+x^2}dy = 0,$$

are of this type. Their solutions are respectively

$$y \sec x - x^2 = C,$$

$$ye^{-x} + \sqrt{1+x^2} = C$$

11 **Change of Variable**—When no convenient method for the integration of a differential equation suggests itself, a procedure which is frequently resorted to is the following one. Some combination of the variables x and y is taken as a new variable, say s , and the differential equation is then expressed in terms of this new variable and one or the other of the original variables. In its new aspect the differential equation may be of a form quite different from its original one. New possibilities for its integration may thus present themselves. It is not always possible to foretell how such a change of variable may profitably be made. In some instances certain combinations of the variables are obviously prominent in the differential equation and the clue as to a desirable change may therein be seen. Some examples will serve to explain and illustrate the procedure.

Consider the differential equation

$$(1+3y+2)x' + (2x+6y+3)dy = 0 \quad (19)$$

The combination $x+3y$ appears with some prominence in this. If we set $s = x+3y$, namely $x = s-3y$, then in virtue of this latter we must set $dx = ds - 3dy$. On substituting these values for x and dx in the equation, this latter becomes

$$(s+2)(ds-3dy) + (2s+3)dy = 0$$

This is found to be an equation with separable variables. By the method of §7 it may be integrated into the relation

$$s - \log(s+3) - y = C$$

On replacing s by its value in terms of the original variables, it is found that

$$x+2y - \log(1+3y+2x) = C,$$

and this is the solution of the given differential equation. As a second case let the differential equation given be

$$2x^2ydx + (x^2y^2 + y^3)dy = 0$$

In this all terms are of the same degree (the third) in x and y ,

and hence a multiplication of the equation by x^{-2} gives it the form

$$2\left(\frac{y}{x}\right)dx + \left[\left(\frac{y}{x}\right)^2 + 1\right]dy = 0$$

The change $s = y/x$, namely $y = xs$, is strongly suggested. In accordance with it $dy = xs' + sdx$ and with the substitution of these values of y and dy , the equation becomes

$$-sdx + (s^2 + 1)(xds + sdx) = 0$$

This has separable variables, and has the solution $\log(s^2 + 3s) = C$. Upon replacing s by its value in terms of x and y the solution of the given equation is obtained, namely

$$\log x + \log\left(\frac{y^2}{x^2} + \frac{3y}{x}\right) = C$$

A standard form of differential equation which yields to this method of integration is the equation

$$\frac{dy}{dx} + P(x)y = Q(x)y^k, \quad (20)$$

in which the coefficients P and Q do not involve y . If $k=1$, the variables are separable, and if $k=0$, the equation is linear. The integration in these cases has, therefore, been already discussed. In the remaining cases, namely $k \neq 0, k \neq 1$, the change of variable $s = y^{1-k}$, reduces the equation to the linear form

DIFFERENTIAL EQUATIONS OF THE SECOND ORDER

12 **The Linear Equation**—The differential equation of the n th order which is of the form

$$a_n \frac{d^2 y}{dx^2} + a_1 \frac{d^{n-1} y}{dx^{n-1}} + \dots + a_{n-1} \frac{dy}{dx} + a_n y = f(x), \quad (21)$$

in which the coefficients a_0, a_1, \dots, a_n , may be functions of x but do not involve y or any of its derivatives, is called the linear differential equation of the n th order. The equation which differs from this only by having zero as its right hand member in the place of $f(x)$, is called the corresponding reduced or homogeneous equation. Certain facts concerning equations of this type greatly facilitate the construction of their solutions. These are primarily the following. If $y_0(x)$ is any solution (particular) of the differential equation (21), and $y_1(x), y_2(x), \dots, y_{p-1}(x)$ are any linearly independent solutions of the corresponding reduced equation, then the relation

$$y = y_0(x) + c_1 y_1(x) + c_2 y_2(x) + \dots + c_{p-1} y_{p-1}(x), \quad (22)$$

in which the coefficients c_1, c_2, \dots, c_{p-1} are arbitrary constants, is also a solution of the equation (21). If, in particular, the number p is n , the solution (22) is the general solution since it involves n arbitrary constants. Because of these facts the integration of an equation (21) is achievable by the determination, in any manner, of a particular solution of that equation, and of n functionally distinct particular solutions of the reduced equation.

Insofar as the application of differential equations to physics and engineering are concerned, the linear type of equation is of very great importance. Since by far the largest number of applications lead, moreover, to differential equations of the second order, we shall confine our discussion to these in the following. Such equations are solvable by elementary methods, as will be shown, whenever the coefficients are constants. When these coefficients are more general functions of x , on the other hand, explicit solutions in simple closed formulas usually do not exist. Because of their very great importance a number of equations of this kind have been endowed with proper names, such as the Bessel equation, the Legendre equation, the Mathieu equation, etc., and volumes have been written about them.

13 **Some Examples from Physics**—When the differential equation (21) is of the second order, it is explicitly

$$a_2 \frac{d^2 y}{dx^2} + a_1 \frac{dy}{dx} + a_0 y = f(x), \quad (23)$$

and its reduced equation is

$$a \frac{d^2 y}{dx^2} + a \frac{dy}{dx} + a y = 0 \quad (24)$$

If a_0 is a constant, it is assumed to be different from zero, since the equation would otherwise be of a lower order than the second.

In §2 the physical problem of a weight suspended from a coiled spring and oscillating in the vertical direction about the point $y=0$ was shown to be formulated by the differential equation (2). It will be observed at once that this equation is of the type (24). Had the position of equilibrium been chosen to be some value of y different from zero, the resulting differential equation would have been of the type (23). In the following, some other formulations from the field of physics are shown to lead to differential equations of these types.

If a body of mass m and weight w is permitted to fall in a vacuum, the pull of gravity exists upon it a force equal to its weight. By Newton's second law of motion this force is equal to the product of its mass by its acceleration, the latter being $d^2 y/dt^2$, if y denotes the distance through which it has fallen. The motion is thus formulated by the differential equation

$$m \frac{d^2 y}{dt^2} = w,$$

and this is of the form (23). For the case of a fall, not in a vacuum, but in a medium, such as air, which resists the motion with a force which is at any instant a constant k times the velocity, the effective downward force is $w - k^2 dy/dt$. The law of motion is accordingly

$$m \frac{d^2 y}{dt^2} = w - k^2 \frac{dy}{dt},$$

and this is again a differential equation of the type (23).

The discharge of an electrical condenser through an inductive coil of wire may also be readily formulated in symbols. The potential difference V between the terminals of the condenser is at each instant proportional to the charge Q upon it, the constant C in the relation $Q=CV$, being called the condenser's capacity. The current I of the discharge is the rate $-dQ/dt$ at which the charge diminishes, and thus $I = -CdI/dt$. The counter e.m.f. interposed by the coil is equal to the coil's inductance L times the rate of current change, and thus the effective voltage is $V - LdI/dt$. This is equal to the current times the resistance R , namely $V - LdI/dt = RI$. Upon substituting the value of I above, this equation becomes

$$V + LC \frac{d^2 V}{dt^2} = -RC \frac{dV}{dt},$$

and this differential equation is of the form (24).

14 A Solution of the Equation with Constant Coefficients—When the coefficients of the equation (24) are constants, as in the case of each of the equations which were derived in §13, the substitution

$$y = e^{rx} \quad (25)$$

with r standing for a constant, leads to the relation

$$(a_0 r^2 + a_1 r + a_2) e^{rx} = 0$$

This is fulfilled if r is a root of the equation

$$a_0 r^2 + a_1 r + a_2 = 0, \quad (26)$$

this being called the auxiliary equation of (24). When this auxiliary equation has two unequal roots, say $r=r_1$ and $r=r_2$, the formula (25) with either one of these values of r solves the differential equation (24). The same is true of the formula

$$y = c_1 e^{r_1 x} + c_2 e^{r_2 x}, \quad (27)$$

irrespective of the values of the constants c_1, c_2 . Since the relation (27) thus involves two arbitrary constants, it is the general solution of the differential equation (24).

The reasoning obviously requires some modification when the auxiliary equation (26) has a multiple root, when, in effect, it has only one root, say $r=r_1$. The exponentials on the right of (27) are then the same, and that relation involves only one arbitrary constant, namely $(c_1 + c_2)$. It is, however, easily veri-

fied that in this case the formula $y = x e^{r_1 x}$ is also a solution of the differential equation. The general solution is, therefore, in this instance given by the relation

$$y = c_1 e^{r_1 x} + c_2 x e^{r_1 x} \quad (28)$$

Let us consider now the equation (23). If a particular solution $y_0(x)$ of this equation is in any way obtainable, the general solution is given at once by the addition of this $y_0(x)$ to the right hand member of the appropriate relation (27) or (28). This was observed in §12, and was formulated in the relation (22). The matter at issue is, therefore, only the deduction of a particular solution $y_0(x)$. There are a number of procedures in common practice for achieving this. One such is the following.

The differential equation (23) may be written in the form

$$\frac{d}{dx} \left(\frac{dy}{dx} - r_1 y \right) - r_1 \left(\frac{dy}{dx} - r_1 y \right) = \frac{1}{a_0} f(x) \quad (29)$$

If the symbol $\varphi(x)$ is introduced with the significance

$$\frac{dy}{dx} - r_1 y = \varphi(x), \quad (30)$$

the equation (29) appears in the form

$$\frac{d\varphi}{dx} - r_1 \varphi = \frac{1}{a_0} f(x) \quad (31)$$

This, however, is a linear differential equation of the first order for the value of $\varphi(x)$, and by the relation (18) (with $c_0=0$) it is fulfilled if

$$\varphi(x) = e^{r_1 x} \int \frac{f(x)}{a_0} e^{-r_1 x} dx$$

The function $\varphi(x)$ has thus been made known, and, this being so, the solution $y(x)$ sought is shown by (30) to be obtainable by the integration of that equation. This is again an equation of the first order and the linear type. As applied to it the relation (18) (with $c=0$) yields

$$y = e^{r_1 x} \int \varphi(x) e^{-r_1 x} dx,$$

and this is the evaluation of the desired particular solution $y_0(x)$.

An example may not be amiss. Let us consider the differential equation

$$2 \frac{d^2 y}{dx^2} - 6 \frac{dy}{dx} + 4y = e^{-3x}$$

The auxiliary equation has the roots $r_1=1$, and $r_2=2$, and thus the general solution of the reduced equation is

$$y = c_1 e^x + c_2 e^{2x}$$

The equation (31) is in this case

$$\frac{d\varphi}{dx} - \varphi = \frac{1}{8} e^{-3x},$$

and a solution of it is $\varphi(x) = -\frac{1}{8} e^{-3x}$. The equation (30) is accordingly

$$\frac{dy}{dx} - 2y = -\frac{1}{8} e^{-3x},$$

and this admits as a solution $y = \frac{1}{40} e^{-3x}$. The general solution of the equation considered is, therefore,

$$y = \frac{1}{40} e^{-3x} + c_1 e^x + c_2 e^{2x}$$

15 The Method of Undetermined Coefficients—A procedure for finding a solution $y_0(x)$ which is in wide practical use, although it is not always applicable, is the following one. Suppose the right hand member $f(x)$ is expressible in terms of the functions of a set $\varphi_1(x), \varphi_2(x), \dots, \varphi_p(x)$, in the manner

$$f(x) = k_1 \varphi_1(x) + k_2 \varphi_2(x) + \dots + k_p \varphi_p(x), \quad (32)$$

with constant coefficients k_1, k_2, \dots, k_p , the functions of this set being such that the derivative of each one of them can also be so expressed. Then if $y_0(x)$ is assumed to be of the form

$$y_0(x) = b_1 \varphi_1(x) + b_2 \varphi_2(x) + \dots + b_p \varphi_p(x), \quad (33)$$

the coefficients $a_1, a_2, \dots, b_1, b_2, \dots$ may be determined. An example will illustrate the way in which this follows.

Consider the differential equation

$$\frac{d^2 y}{dx^2} + 3 \frac{dy}{dx} + 2y = 4x + 11 \cos x$$

In this case the right hand member is expressible in the form (32) with $\varphi_1 = x$, $\varphi_2 = 1$, $\varphi_3 = \cos x$, $\varphi_4 = \sin x$, and the derivative of each of these can also be so expressed. Hence if we assume

$$y_0 = b_1 x + b_2 + b_3 \cos x + b_4 \sin x,$$

the result of substituting this into the differential equation is the relation

$$2b_1 x + (3b_2 + 2b_3) + (b_3 + 3b_4) \cos x + (b_1 - 3b_4) \sin x = 4x + 11 \cos x$$

Equating coefficients of similar terms we find that $2b_1 = 4$, $3b_2 + 2b_3 = 0$, $b_3 + 3b_4 = 11$, $b_1 - 3b_4 = 0$. These equations determine the evaluations $b_1 = 2$, $b_2 = -3$, $b_3 = -1$, $b_4 = 3$, and thus

$$y_0 = 2x - 3 - \cos x + 3 \sin x.$$

The methods of this and the preceding sections, as well as a number of other methods, are set forth in the references (5), (8), (9), (12) and (15).

16 The Method of Power Series—When the coefficients of the differential equation (23) are not constants but are continuous functions of x , the character of the solutions near any specific point x depends significantly upon whether the leading coefficient $a_0(x)$ is or is not zero at this point. In the former case the point is called a singular point, and such points are classified into several different categories. For discussions of these matters the references (2), (3), (8) and (13) should be consulted. We shall assume in proceeding that for the values of x in question $a_0(x) \neq 0$, and that this and the other coefficients as well as the function X , are either polynomials or are representable in power series. The method is one of assuming a solution to be given by an infinite series

$$y = c_0 + c_1 x + c_2 x^2 + c_3 x^3 + \dots \quad (34)$$

and then, by the substitution of this form into the equation, determining the coefficients. An example will make the procedure clear.

Thus consider the differential equation

$$(1-x) \frac{d^2 y}{dx^2} - 4 \frac{dy}{dx} + \frac{2}{1-x} y = 0$$

Since from (34)

$$\frac{dy}{dx} = c_1 + 2c_2 x + 3c_3 x^2 + 4c_4 x^3 + \dots,$$

$$\frac{d^2 y}{dx^2} = 2c_2 + 6c_3 x + 12c_4 x^2 + \dots,$$

whereas

$$\frac{2}{1-x} = 2 + 2x + 2x^2 + 2x^3 + \dots,$$

the terms of the differential equation (35) are respectively

$$(1-x) \frac{d^2 y}{dx^2} = 2c_2 + (6c_2 - 2c_1)x + (12c_4 - 6c_3)x^2 + \dots,$$

$$-4 \frac{dy}{dx} = -4c_1 - 8c_2 x - 12c_3 x^2 + \dots,$$

$$\frac{2}{1-x} y = 2c_0 + (2c_0 + 2c_1)x + (2c_0 + 2c_1 + 2c_2)x^2 + \dots$$

The result of substituting the form (34) into the differential equation is thus the relation

$$(2c_2 - 4c_1 + 2c_0) + (6c_2 - 10c_1 + 2c_1 + 2c_0)x + (12c_4 - 18c_3 + 2c_2 + 2c_1 + 2c_0)x^2 + \dots = 0$$

This is fulfilled if the coefficient of each power of x is zero, namely if

$$2c_2 - 4c_1 + 2c_0 = 0,$$

$$6c_4 - 10c_3 + 2c_2 + 2c_0 = 0,$$

$$12c_6 - 18c_5 + 2c_4 + 2c_2 + 2c_0 = 0,$$

If any choice is made of c_0 and c_1 these equations serve in turn

to give evaluations for c_2, c_3, c_4, \dots

Specifically let the choice $c_0 = 0$, $c_1 = 1$ be made. The values $c_2 = 2$, $c_3 = 3$, $c_4 = 4$, ... are found to result, and the series

$$y_1 = x + 2x + 3x^2 + 4x^3 + \dots$$

is accordingly a solution. The alternative choice $c_0 = 1$, $c_1 = 0$, leads to the values $c_2 = -1$, $c_3 = -1$, $c_4 = -3$, ... and the series

$$y_2 = 1 - x - 2x^2 - 3x^3 - 4x^4 - \dots$$

is a second solution. When combined with arbitrary constants as multipliers these yield the general solution. The values of x for which solutions are thus obtained, are, of course, only those for which the infinite series are convergent.

17 Other Branches of the Subject—The field of differential equations is so vast that any short but adequate summary of it is quite impossible. It must suffice, therefore, to mention, prominent ramifications of it. In the place of only a single differential equation the object of study may be a simultaneous system of such equations. The formulation of the laws of dynamics frequently leads to such systems. In many cases a single differential equation of the n th order is advantageously replaceable by a system of n simultaneous equations each of which is of the first order. On this subject material is to be found in the references (1), (5), (8) and (9).

Certain problems call for the solutions of differential equations of a type called total differential equations. They are typified by the equation of the form

$$P(x, y, z)dx + Q(x, y, z)dy + R(x, y, z)dz = 0$$

(cf. the references (5), (8) and (9)).

When the number of independent variables is greater than one, the derivatives which come into question are partial derivatives, and equations involving them are partial differential equations. The theory of such equations is extensive and on the whole quite intricate. They are, however, of the greatest importance in the applications of mathematics to the sciences. Problems, such as the flow of heat in a body, the vibrations of stretched wires or membranes, the flow of electric current in cables, the deflections of elastic beams when loaded and others in great variety, require for their formulations partial differential equations. Elementary theory concerning these is to be found in the references (3), (5), (9), (10), (12) and (15). More advanced material is presented in the references (4) and (6).

As in the case of ordinary differential equations, so also in partial equations, the physical problem calls not merely for a solution but for the solution that also fulfills certain auxiliary conditions. A fundamental method for dealing with such problems, known as the method of separation of variables, effectively replaces the partial differential equation by certain related families of ordinary differential equations with appropriate boundary conditions. The theory of such families, which are generally designated as differential equations involving a parameter, is known as the theory of boundary value problems. This theory is the principal subject of the references (3) and (13), and is also treated in (4) and (8). Much theory of this kind, however, is only accessible in the literature of original mathematical research.

DIFFERENTIAL FORMS The theory of differential forms is a branch of mathematics which presupposes several other branches, including differential calculus, algebra, and theory of functions. In essence, it is a theory of transformations of co-ordinates, such as

$$\begin{aligned}x &= f(x', y', z') \\ y &= g(x', y', z') \\ z &= h(x', y', z')\end{aligned}\quad (1)$$

which are differentiable and have single-valued inverses. This transformation carries any set of values of the variables x, y, z into a definite set of values of x', y', z' . It also induces the transformation of differentials

$$\begin{aligned}dx &= \frac{\partial f}{\partial x'} dx' + \frac{\partial f}{\partial y'} dy' + \frac{\partial f}{\partial z'} dz', \\ dy &= \frac{\partial g}{\partial x'} dx' + \frac{\partial g}{\partial y'} dy' + \frac{\partial g}{\partial z'} dz', \\ dz &= \frac{\partial h}{\partial x'} dx' + \frac{\partial h}{\partial y'} dy' + \frac{\partial h}{\partial z'} dz'\end{aligned}\quad (2)$$

Now consider a function

$$P(x, y, z)dx + Q(x, y, z)dy + R(x, y, z)dz, \quad (3)$$

in which P, Q , and R are differentiable functions of x, y , and z . This function has a definite numerical value whenever definite values are assigned to the variables x, y, z, dx, dy, dz . If we substitute for these variables according to the equations (1) and (2) we obtain a function

$$P'(x', y', z')dx' + Q'(x', y', z')dy' + R'(x', y', z')dz', \quad (4)$$

which has the same value as (3) whenever $x', y', z', dx', dy', dz'$ and x, y, z, dx, dy, dz are assigned values which are related by the equations (1) and (2). The two functions (3) and (4) are representations or components in different co-ordinate systems of the same differential form. In this case, since the expressions (3) and (4) are both linear functions, the differential form is said to be linear.

The components of a differential form can also be quadratic in the differentials, for example,

$$Edu^2 + 2Fdu dv + Gdv^2, \quad (5)$$

in which E, F , and G are functions of two variables u and v . In general, the components of a differential form are required to be functions which are differentiable in the variables x, y , etc., and differentiable and homogeneous in the differentials dx, dy , etc. In the cases usually considered they are homogeneous polynomials in the differentials. They may also be functions of several sets of differentials. For example, the quadratic form (5) is intimately related to the bilinear form,

$$Edu\delta u + F(du\delta v + dv\delta u) + Gdv\delta v$$

It is obviously a fundamental problem to determine whether two differential expressions, such as (3) and (4) for example, are or are not components of the same differential form. This is known as the equivalence problem. The study of this problem, as well as of related problems, has led to the discovery of differential invariants of various kinds. The simplest of these are functions formed from the given form which are unchanged in value by transformations of coordinates. For example, an invariant of (3) is the bilinear form,

$$\begin{aligned}\left(\frac{\partial P}{\partial y} - \frac{\partial Q}{\partial x}\right)(dx\delta y - dy\delta x) + \left(\frac{\partial Q}{\partial z} - \frac{\partial R}{\partial y}\right)(dy\delta z - dz\delta y) \\ + \left(\frac{\partial R}{\partial x} - \frac{\partial P}{\partial z}\right)(dz\delta x - dx\delta z)\end{aligned}$$

This example illustrates one of the uses to which differential invariants are put. For the vanishing of this bilinear form is a necessary and sufficient condition that (3) be a "complete differential." In other words, there exists a function $F(x, y, z)$ such that

$$dF(x, y, z) = Pdx + Qdy + Rdz,$$

if and only if this bilinear form vanishes. Other properties of

the differential form (3) are expressed by the vanishing of other invariants. Indeed, the typical way of saying anything about a differential form is to assert that such and such an invariant vanishes—and a very large proportion of the theorems of geometry and physics reduce to such statements.

Returning to the example of a linear differential form which has the components (3) and (4) in two coordinate systems we find, on carrying out the substitution of (1) and (2) in (3), that

$$\begin{aligned}P'(x', y', z') &= P \frac{\partial f}{\partial x'} + Q \frac{\partial g}{\partial x'} + R \frac{\partial h}{\partial x'}, \\ Q'(x', y', z') &= P \frac{\partial f}{\partial y'} + Q \frac{\partial g}{\partial y'} + R \frac{\partial h}{\partial y'}, \\ R'(x', y', z') &= P \frac{\partial f}{\partial z'} + Q \frac{\partial g}{\partial z'} + R \frac{\partial h}{\partial z'}.\end{aligned}\quad (6)$$

In these equations P stands for the function of x', y', z' , obtained by substituting (1) in $P(x, y, z)$, similarly Q and R . In the language of Tensor Analysis (*q.v.*) the equations (6) state that the coefficients of a linear differential form are the components of a covariant vector. In like manner we can work out the equations of transformation, analogous to (6), of the coefficients of a differential form of any degree. It comes out that whenever the differential form is a polynomial in the differentials, the coefficients are the components of a covariant tensor. The theory of these differential forms is therefore co-extensive with that of covariant tensors.

The theory even of linear differential forms is very extensive and has applications in a wide variety of fields of mathematics and physics. We need only mention line integrals, vector analysis (*q.v.*), and electricity and magnetism (*qq.v.*). The higher theory of linear differential forms and systems of linear differential forms is to be found in mathematical books usually under the heading "The problem of Pfaff," so called because the first investigations of the subject were made by Pfaff in 1814 and 1815.

The theory of quadratic differential forms was initiated in 1827 by Gauss, who showed that the metric properties of surfaces depend on forms of the type (5). This work of Gauss is also the foundation of modern differential geometry (*metric*) (*q.v.*). From the point of view of differential forms his chief contribution was the discovery of an invariant, called the curvature, which is a function of E, F , and G , and then first and second derivatives, which is unaltered by all differentiable transformations of the variables u, v . The next important step was taken by Riemann, who in 1854 outlined the theory in its full generality and used it as the basis of what has come to be known as Riemannian geometry. He also showed that the curvature of Gauss must be replaced in the general case by what is now called the curvature tensor. The work of Riemann was followed immediately by that of Christoffel and Lipschitz. The former introduced the functions often called Christoffel symbols or the components of affine connection, and gave a solution of the equivalence problem. Lipschitz developed the calculus of variations (*q.v.*) side of the subject and also the system of normal coordinates which had been sketched by Riemann. This work was followed by a long series of researches by many mathematicians.

The theory of quadratic differential forms has found many applications in geometry and physics, notably in dynamics. In recent years it has received a great deal of attention and been generalized in various directions because it is the foundation of Einstein's theory of relativity. In the researches of Einstein, as extended by Weyl and others, the phenomena of gravitation and electricity are described by means of a quadratic and a linear differential form restricted by the vanishing of certain invariants.

The theory of differential forms has been extended and generalized along various directions. The theories of topological spaces and the modern differential calculus in linear topological spaces have played and will no doubt continue to play a fundamental role in these developments.

DIFFERENTIAL GEOMETRY (METRIC) Differential geometry is the theory of the properties of curved surfaces and higher manifolds in the vicinity of a general one of its elements, for example, a study of the properties of a curve in the vicinity of one of its points is a study in differential geometry. Straight lines, circles, planes and spheres have the property that any part of any one of them has the same shape as any other part. Other curves and surfaces do not have that property. The study makes much use of the calculus. Metric differential geometry concerns itself primarily with those properties with which the notion of measurement is associated.

The older metric differential geometry assumed that the curves and surfaces lay in Euclidean space of three dimensions, that is in ordinary space. It could be defined as the study of the differential properties of curves and surfaces invariant under rigid motions. The measurement of magnitudes was based on Euclidean measure. The Euclidean distance between two points whose rectangular Cartesian co-ordinates are (x, y, z) , $(x+d\bar{x}, y+d\bar{y}, z+d\bar{z})$ is given by the formula

$$(ds)^2 = (d\bar{x})^2 + (d\bar{y})^2 + (d\bar{z})^2 \quad (1)$$

The equation of a curve C , defined to be the locus of a one parameter family of points, may be written in the form

$$x = f_1(t), \quad y = f_2(t), \quad z = f_3(t) \quad (2)$$

where t is the parameter. A value t of the parameter determines a point P , and a value $t+\Delta t$ determines a second point Q . If the line PQ approaches a limiting position as Δt approaches zero that limiting position is called the *tangent line* to C at P . This example shows that the property of a curve having a tangent line at a point is a differential property since it requires a knowledge of the curve in the vicinity of P and involves the limiting process. Computing the differentials dx, dy, dz from (2) and substituting these in (1), there is computed the length of an arc of C by integrating an expression of the form $ds = F(t)dt$.

If all of the points of a curve lie in a plane the curve is said to be a *plane*, otherwise it is *skew*. Let P be any point on C , and Q_1, Q_2 be any two other points on C in the vicinity of P . The plane determined by P, Q_1, Q_2 assumes a limiting position called the *osculating plane* of C at P as Q_1, Q_2 approaches P independently along C . The circle determined by P, Q_1, Q_2 assumes a limiting position called the *osculating circle* or *circle of curvature*. It follows that the osculating plane of a plane curve is the plane of the curve, and the osculating circle of a circle is that circle. The normals to a curve at a point all lie in a plane called the *normal plane*. That normal which lies in the osculating plane is called the *principal normal*, and that one perpendicular to the osculating plane is called the *binormal*.

The rates of change, κ and τ , of the angles which the tangent and binormal respectively make with a fixed line per unit arc length s are called the *curvature* and *torsion* of C at P . The curvature κ is the reciprocal of the radius of the circle of curvature, whence the name of that circle. The quantities κ, τ and s are intrinsic properties of the curve, in the sense that given κ and τ as functions of s , the curve is uniquely determined except for its position in space. For example, if the curvature is a constant and the torsion is zero, the curve is a circle. Or again, if the curvature and the torsion are constants, the curve is a helix, that is, it forms the threads of a cylindrical screw (or bolt). The reader is referred to the many treatises and texts for further information concerning the theory of curves.

A surface S may be defined as the locus of a two parameter family of points. Its parametric equations may be written in the form

$$x = f_1(u, v), \quad y = f_2(u, v), \quad z = f_3(u, v), \quad (3)$$

a formulation due to K. F. Gauss. A curve C on S may be defined by an equation of the form

$$v = v(u) \quad (4)$$

If the point P on S is an ordinary point of S , that is, is not a point like the vertex of a cone, all of the tangents to all of the curves on S through P lie in a plane called the *tangent plane*. The line perpendicular to the tangent plane to S at P is called the *normal* to S at P . Usually the tangent plane to a surface depends on two parameters, if it depends only on one, the surface S is said to be *developable*. Such a surface may be rolled out or *developed* on a plane. Cones and cylinders are examples of developable surfaces. Except for these two kinds of developable surfaces, a developable surface may be visualized as the locus of the tangents to a skew curve.

If dx, dy, dz are computed from (3) and substituted in (1) there is obtained an expression of the form

$$ds^2 = Edu^2 + 2Fdu dv + Gdv^2 \quad (5)$$

The differential form appearing in the right member of (5) is called the *first fundamental form* of S , and the coefficients E, F, G are called the *first fundamental coefficients*, they involve only the first derivatives of x, y, z with respect to u and v . Using (4) the length of a curve may be found from (5) by integrating an expression of the form $ds = f(u)du$. Angles between curves on S , and areas of portions of S involve E, F and G only.

If one imposes the condition on a curve C on S given by (4) that at each of its points its osculating plane coincides with the tangent plane to S at those points the differentials du, dv satisfy an equation of the form

$$Ddu^2 + 2D'udv + D''dv^2 = 0 \quad (6)$$

Such a curve is called an *asymptotic curve*. The quadratic form appearing in the left member of (6), into which a convenient factor of proportionality has been introduced, is called the *second fundamental form*, and D, D', D'' are called the *second fundamental coefficients*. These six fundamental coefficients subject to certain restrictions called the Gauss-Codazzi conditions play a role in the theory of surfaces similar to that played by the curvature and torsion in the theory of curves, in the sense that given these six coefficients as functions of u and v the surface is uniquely determined except for its position in space. For example, if the second fundamental coefficients are proportional to the first fundamental coefficients, the surface is a sphere.

Suppose that a curve C_1 through a point P on S is determined in such a manner that the tangents to C_1 at its points of intersection with a given fixed curve C through P form a developable surface, that is, they are tangent to a third curve C_2 . The tangents to C_1 and C_2 are called *conjugate tangents*, implying that the roles of C_1 and C_2 may be interchanged. Any tangent to S at P has a conjugate tangent. Two sets of curves on S having for their tangent lines conjugate tangents form a *conjugate net*. The determination of conjugate tangents involves the second fundamental coefficients.

A section of a surface by a plane through the normal at P is called a *normal section*, and the curvature of the normal section is called the *normal curvature*. The normal curvature usually depends on the sectioning plane, if at a particular point the normal curvature is the same for every section, the point is called an *umbilical point*. For example every point on a sphere is an umbilical point. If P is not an umbilical point, there exist two sections or S at P such that one section has maximum and the other minimum curvature. These sections lie in perpendicular planes. The tangents to the sections are called *principal directions*. The principal directions are perpendicular and conjugate. The curves on S which are tangent at every point on S to the principal directions are called the *lines of curvature*. Their dif-

ferential equations involve both the first and second fundamental coefficients since they are both orthogonal and conjugate. The normals to S at points of a line of curvature form a developable surface.

The sum of the maximum and minimum normal curvatures is called the *mean curvature*, and their product is called the *Gaussian curvature* K . The Gaussian curvature may be described geometrically as follows: let Σ be a small portion of S including a point P , and let C be the bounding curve of Σ . Draw lines through the centre of a sphere with unit radius parallel to the normals of S at points of C . These lines will intersect the sphere in points of a closed curve C' . The limit as Σ shrinks to P of the ratio of the area enclosed by C' to the area of the portion ω of S is the Gaussian curvature K , the value of K is given by the formula

$$K = \frac{DD'' - D'^2}{EG - F^2} \quad (7)$$

Due to the Gauss-Codazzi conditions, K may be expressed in terms of E, F, G and their derivatives. Hence, the Gaussian curvature depends on the surface alone and not on the space in which the surface lies. The Gaussian curvature of a developable surface is zero, it is a positive constant for a sphere. A surface for which K is a negative constant is called a *pseudo-sphere*.

Through each point P of S and in each direction through P there is a curve whose osculating plane passes through the normal to S at P . Such a curve is called a *geodesic* since among them are the curves of shortest length on S . The geodesics on a sphere are the great circles. The differential equation of the geodesics involve only E, F, G and their first derivatives.

One of the important invariants of a curve on a surface is called the *geodesic curvature* of the curve. This invariant may be described in the following manner. Let there be given a curve C through a point P on S . Draw lines through the points of C parallel to the normal to S at P . These lines intersect the tangent plane to S at P in the points of a curve C' . The curve C' being plane has zero torsion, the curvature of C' at P is called the geodesic curvature of the given curve C at P . Another definition of the geodesic curvature indicates more clearly the reason for its name. Consider on C the point P and a second point P' on C at a distance of s from P measured along C . Let g and g' be geodesics tangent to C at P and P' respectively. Let these geodesics intersect at an angle of ϕ . Then the limit of ϕ/s as s approaches zero is the geodesic curvature of C at P . It is evident from this definition that the geodesic curvature of a geodesic is zero at each of its points, and conversely if the geodesic curvature of a curve is zero at each of its points, the curve is a geodesic.

Another invariant of a curve on a surface is called the *geodesic torsion* of the curve. Let g be the geodesic tangent to C at P . The torsion τ_g of the geodesic g at P is called the geodesic torsion of C at P . In particular the geodesic torsion of a line of curvature is zero.

It is not necessary to consider a surface as being immersed in Euclidean space or in any surrounding space for that matter. One may define the element of arc length ds by the formula

$$ds^2 = Edx^2 + 2Fdx dy + Gdy^2, \quad EG - F^2 > 0$$

Definitions of lengths of curves, magnitudes of angles between curves, geodesics, curvature or in fact anything which involves only E, F, G may be made. We say that such a geometry on S is *Riemannian*. Or more generally let a point be defined as the ordered set of numbers (x^1, x^2, \dots, x^n) and the distance ds between that point and $(x^1 + dx^1, x^2 + dx^2, \dots, x^n + dx^n)$ be defined by the formula

$$ds^2 = g_{ij} dx^i dx^j \quad (8)$$

wherein g is taken to be ± 1 to insure that ds^2 be positive. Lengths of curves, magnitudes of angles, geodesics, etc. may be defined in terms of the g 's. Just as the Euclidean metric (1) induces the Riemannian metric (8) on a surface, the metric defined by (8)

induces a metric on a subspace $v = v^i(u^1, u^2, \dots, u^l)$, $l \leq n$. This metric will be of the form $ds^2 = g_{ab} du^a du^b$. That such a definition of a metric is not necessarily Euclidean follows from the fact that there may not be (and there usually isn't) a transformation $v = v^i(y^1, y^2, \dots, y^l)$ such that (8) reduces to the simple Euclidean form

$$ds^2 = (dy^1)^2 + (dy^2)^2 + \dots + (dy^l)^2$$

The tensor calculus, or absolute calculus of Ricci is a convenient tool for studying this Riemannian or non-Riemannian geometry.

DIFFERENTIAL GEOMETRY (PROJECTIVE)

Projective differential geometry studies those properties of a geometric figure in the vicinity of one of its general elements which are unchanged by the general projective transformation. For example, the property that a curve have a tangent (or not have a tangent) at one of its points is a projective differential property of the curve at that point. The possession of an osculating plane by a curve at one of its points is a projective differential property of the curve at that point. However the existence of geodesics on a surface is not a projective property of the surface since the possession of a normal is not a projective property, or since the concept of length is not a projective concept.

At least three methods of studying projective differential properties of figures have been used. These three methods use respectively defining differential equations, power series expansions of the projective co-ordinates of a point of the figure in terms of a parameter or differential forms. The first and the last of these methods may use the tensor calculus, all use the calculus.

The reader is doubtless familiar with the fact that if the co-ordinate system is uniquely defined by the curve, the coefficients of the equation of the curve express in some fashion geometric properties of the curve. For example, if, as in elementary analytic geometry, the co-ordinate axes are chosen as the major and minor axes of an ellipse, the equation of the ellipse becomes

$$x^2/a^2 + y^2/b^2 = 1$$

The geometric interpretations of the numbers a and b appearing in the coefficients are of course familiar. In a similar manner, if the co-ordinate system, the triangle of reference, be chosen in a proper and unique manner, the equation of a plane curve may be written in the form

$$y = x^2 + ax^3 + bx^4 + (b + 2a^2)x^5 + \dots$$

Every coefficient in this power series is an absolute invariant of the curve under the general projective transformation, and hence they express all of the projective differential properties of the curve at the origin. The co-ordinate system is determined by using among other concepts, the concepts of tangent line, osculating conic and osculating cubic. The notion of a tangent line to a curve at a point on the curve is of course familiar, the osculating conic of a curve at a point O may be defined as the limit of the conic determined by the point and four other points on the curve as these latter points approach the given point O independently along the curve. The osculating cubic is defined similarly using the fact that a plane cubic is determined by nine unspecialized points. Since the concept of limit is so prevalent in the study of projective differential properties, it follows that

the calculus is a much used tool in the study. The reader will find full details of these and other matters concerning plane and skew curves in the references at the end of this section.

The locus of a two parameter family of points is called a surface S . A curve C on S is called an asymptotic curve if the osculating plane to C at each of its points coincides with the tangent plane to S at those points. There are ordinarily two one parameter families of asymptotic curves on a surface in a projective space of three dimensions, if there are less the surface is developable, if there are more the surface is a plane. Excluding the developables and planes, and using the asymptotic parameters as parameters for the surface, the homogeneous projective co-ordinates may be chosen so as to satisfy a system of differential equations known as the Fubini differential equations, namely

$$\begin{aligned}\frac{\partial^2 v}{\partial u^2} &= \frac{\partial \theta}{\partial u} \frac{\partial x}{\partial u} + \beta \frac{\partial x}{\partial v} + p x, \\ \frac{\partial^2 x}{\partial v^2} &= \gamma \frac{\partial x}{\partial u} + \frac{\partial \theta}{\partial v} \frac{\partial x}{\partial v} + q x, \\ \theta &= \log(\beta \gamma)\end{aligned}$$

The coefficients β , γ , p , q of this system are invariants of the surface.

Among the projective properties of a surface at one of its points, is the "order of contact" of the surface with a second surface. In particular there is a three parameter family of quadric surfaces having second order contact with S at a point O . Each of these quadrics intersects S in a curve with a triple point at O . If the quadrics are chosen so that the tangents at O to this curve of intersection are apolar to the asymptotic tangents at O , the quadrics are called *quadrics of Darboux*, and the triple point tangents are called *tangents of Darboux*. There is a one-parameter family of quadrics of Darboux at each point of S . Among these are many special quadrics, the *quadric of Lie* being probably the most interesting. It may be described in the following manner. Construct at O and at two other points P_1 , P_2 on an asymptotic curve C through O the tangents to the other asymptotic curves through these points. These three tangents determine a quadric whose limit as P_1 and P_2 approach O along C is the quadric of Lie.

A two parameter family of lines is called a *congruence*. For example, the metric normals to a surface form a congruence. If to a point O on S there is associated a line which varies with O the totality of these lines forms a congruence. As O moves along a properly chosen curve on S , the associated line of the congruence is tangent to a curve, that is, the line generates a developable surface. Ordinarily there are two one-parameter families of such curves on S . They are said to *correspond* to the developables of the congruence. If now a congruence is composed of lines through the points of a surface S but not lying in the tangent plane to S at those points, the reciprocal polars of these lines with respect to any quadric of Darboux form a congruence, the lines of which lie in the tangent planes of S but do not pass through their points of contact with S . Such pairs of congruences are called *reciprocal congruences*. Many pairs of reciprocal congruences have been studied. Among them are the *directrix congruences of Wilczynski*. These may be defined in the following simple manner. If the two sets of curves in S corresponding to the developables of a pair of reciprocal congruences coincide, then these congruences are the *directrix congruences* of Wilczynski.

In attempts to find a congruence which plays a role in projective geometry similar to that played by the congruence of metric normals, the concepts of conjugacy of tangent lines and *conjugate nets* are fundamental. These may be described briefly in the following manner: a tangent line to S at a point and its harmonic conjugate with respect to the tangents to the asymptotic curves through the point are called *conjugate tangents*. If one of a pair of conjugate tangents is chosen as the tangent to the curves of a one-parameter family of curves, the other of the pair is tangent to the curves of a second one-parameter family. Such two sets of curves form a *conjugate net*. Another characteristic property of conjugate nets may be stated in the follow-

ing manner: as a point O moves along one curve of a conjugate net, the tangents at O to the other curve of the conjugate net through O generate a developable surface. As a point moves along a curve on S , the metric normal generates a ruled surface. If the curve is chosen as a line of curvature, this ruled surface is a developable surface. The net composed of the lines of curvature is a conjugate net, and corresponds to the developables of the metric normal congruence. It is said that the metric normal congruence is *conjugate to the surface*. In general any congruence composed of lines protruding from the surface is said to be conjugate to the surface if the curves corresponding to its developables form a conjugate net. The reciprocal congruence of a congruence conjugate to a surface is said to be *harmonic to the surface*, its developables also correspond to a conjugate net on S . There are many congruences in projective differential geometry which could serve as a generalized normal congruence in the sense that the congruence is geometrically determined by the surface and is conjugate to the surface. Among these is the so-called Green-Fubini projective normal.

The curve whose tangents form a developable surface is called the *cuspidal edge of the surface*. From the characteristic property of conjugate tangents through O , each of the pair is tangent to a cuspidal edge at the *ray-point*. The two ray points so defined determine the ray of the net at O . The osculating planes at O of the curves of the net intersect in the axis of the net. The ray and axis, and the congruences generated by them have been the subjects of much study.

Geodesics play an important role in metric differential geometry. Attempts have been made to generalize the concept of geodesics to projective geometry. In the first place the extremals of the invariant integral $\int \sqrt{\beta \gamma} du dv$ are called *projective geodesics*. The osculating planes to all of the projective geodesics through a point is a cone of class three, the cusp axis of this cone is the projective normal of Green and Fubini. A second generalization of geodesics is the *union curves* of a congruence. They are the curves on S at each of whose points the osculating plane contains the line of the congruence through the point. This is a direct generalization of the concept of a geodesic since the union curves of the metric normal congruence are the geodesics.

Considerable attention is paid in projective differential geometry, as in metric, to general types of transformations of surfaces. One of the most important of these is the transformation F . This transformation may be described in the following simple manner. Two surfaces in one to one-point correspondence are said to be related by the transformation F if the developables of the congruence of lines joining corresponding points correspond to conjugate nets on each of the surfaces, these conjugate nets also corresponding in the one-to-one correspondence between the surfaces. Other transformations of conjugate nets into conjugate nets form an important part of the theory of transformation of surfaces in projective differential geometry. The reader is referred to the treatises below for complete details of these and related topics.

DIFFERENTIAL PARALLELISM • SEE TENSOR ANALYSIS

DIFFERENTIAL PSYCHOLOGY is that branch of psychology which deals with differences among individuals and groups in mental traits and performances. Individual differences are attributable broadly to the two closely interwoven forces of nature and nurture, or heredity and environment. In the first category are intrinsic factors, race, sex, age, immediate ancestry, in the second category are extrinsic factors, the social, educa-

tional, cultural, physiological and other influences which shape and mould the developing individual from birth until death.

In a general sense, the complex and more recently acquired traits tend to be more variable than the simple, biologically more fundamental. The feeble minded, for example, differ least from the normal in physical and motor abilities and most in the ability to use language, deal with ideas and employ abstract thought. Even among groups relatively homogeneous in general ability, we find greater variability in those functions requiring the education of intricate verbal relations, learning and association, than in those functions requiring speed of voluntary movement, perception or rote memory. Individuals do not fall into sharply separated groups or "types" in mental or in physical traits. People differ widely, for example, in the vividness and the character of the mental imagery which they possess. In other traits the same condition obtains, mediocrity is the status most often encountered, marked superiority or inferiority being relatively and about equally infrequent.

Careful studies of primitive peoples have shown that these groups do not differ markedly from modern Europeans in sensory equipment such as keenness of vision and hearing, sensitivity to pain and pressure and delicacy of the skin senses. Simple intelligence tests of the form board variety (a form board is a board containing cutout depressions into which blocks of different shapes and sizes are to be fitted) show no marked differences between whites and many primitive folk (e.g., Eskimos, American Indians, etc.) although a few groups, the Igorot, the Negro and the Pygmies, do no better than low grade and even imbecile whites. The inferiority of the Negro to the white in innate mental capacity has often been asserted as the result of comparative studies, but it is difficult to say how much of the differences found is to be attributed to cultural, rather than to native factors. It is not known, for example, whether the superior performance of northern American Negroes as compared with southern is attributable to selective migration of the more able, or whether it is the result of better social and educational advantages. Negro high school children in New York city remain in school longer, are older on the average and are inferior in school work to whites of approximately the same social status. The greater admixture of white blood, the closer does the Negro approach the white in performance. Intelligence tests given in 1917-18 to large groups of white and Negro soldiers in the U.S. army place the Negro consistently below the white in both language and non-language functions. Several investigations have suggested that the Negro is more overtly emotional and less inhibited in his reactions than is the white. The American Indian ranks generally below the white man on tests of mental capacity, the greater the race admixture, the smaller the deviation from the performance of the white. There is evidence indicating that the American Indian, while slower in motor performances than the white, is more accurate and painstaking.

In comparative studies of general intelligence made in America, Chinese children have ranked slightly below whites in English language tests. Chinese and Japanese children do not differ significantly in intelligence, however, from comparable groups of whites, when due allowance is made for cultural and social status. The most extensive comparative data on intelligence differences among national groups are those obtained from tests given in the U.S. army during World War I. These tests indicated a superiority of those foreign-born men from northern European countries (the Nordics) over those from central and southern European countries (the Alpines and the Mediterraneans). Differences in selection plus differences in language, schooling and cultural background probably account for most if not all of the difference found.

Comparative studies of men and women have indicated few differences in mental ability which might be attributed to the factor of sex apart from social and cultural influences. Differences within either sex are much greater than differences between the sexes. Women have been reported to have a finer sense of touch, better colour discrimination and to be faster in verbal association, men to be superior in the discrimination of differ-

ences in weight and in visual magnitudes and in the speed of motor response (reaction time). In general females are superior to males in tests of memory, males to females in tests of logical construction and in problems involving abstract and spatial relationships. Women are probably somewhat less stable emotionally than men. It has been asserted that women are more interested in people, more religious, more patient and more sympathetic, while men are said to be more interested in physical activity, to possess a superior sense of humour and to be more independent. Girls are definitely better in school work than boys. This result has been explained as owing to the slower physical development of boys, to the greater docility of girls and to native differences in ability.

The fact that men have excelled women in practically every field of endeavour is probably to be attributed to social, cultural and traditional factors, and to the greater physical strength and endurance of men, rather than to native differences in endowment. One explanation is based upon the reputed greater variability within the male sex. Greater variability, i.e., greater range of ability, would tend to produce more gifted men than women, even though the average man and average woman rank about the same in mental ability. The existence of greater variability in the male sex has been disputed by competent investigators.

Investigators are fairly well agreed that there is a regular and progressive increase in mental ability from infancy up to and through adolescence. This mental growth roughly parallels the steady increase in physical size and strength. The claim has been made (the Iowa studies) that the IQ can be greatly increased by special school training, but the evidence on this point is not convincing to most psychologists. After adolescence growth in mental abilities (perception, associative learning, memory) increases slowly if at all, while in many cases it ceases altogether. Performances which are based upon experience, such as judgment, reasoning ability in practical situations and rational learning, probably improve up through middle life and show no great loss until old age.

There is a general loss in the speed and flexibility of mental processes in old age. Sensory acuity in general—auditory, visual and tactual—is considerably reduced and there is some loss in learning ability, speed of reaction and memory. Curiosity and enthusiasm are lost as physical and mental vigour wane. A part at least of the drop in test score with increasing age can be attributed to the loss in speed of response, and a part to the lack of recent practice with the kind of operations demanded by the tests. Suggestibility, or the ability to resist suggestion, is another complex trait which has been found to vary with age and sex. Tests applied to children indicate that the ability to resist suggestion increases progressively with age from six or seven years through adolescence.

The influence of immediate ancestry is best studied by comparing the resemblances shown by twins, siblings and unrelated persons. Twins are more alike mentally and physically than siblings (ordinary brothers and sisters). The fact that older twins are no more alike than younger twins argues for the greater potency of heredity in determining behaviour. Brothers, and brothers and fathers, are more alike as measured by the correlation of mental and physical traits than are unrelated persons. A considerable part of the resemblances noted among those of the same family or closely related families, such as habits of speech and thought, common opinions, ideas and attitudes, arises from a common fund of environmental stimuli and associations.

See A. Anastasi, *Differential Psychology* (1937), E. B. Greene, *Measurements of Human Behaviour* (1941). (H. E. G.)

DIFFERENTIATION, a term used in biology signifying the evolutionary process, by which certain modifications of the body both structural and functional take place in plants and animals. In the vegetable kingdom the evolution of growth is usually from the simple to the complex form, the organs developing into more specialized parts of the body. See PLANTS and PLANT SCIENCE, EXPERIMENTAL EMBRYOLOGY, DIFFERENTIATION. See also CALCULUS, DIFFERENTIAL and INTEGRAL.

DIFFRACTION *see* LIGHT

DIFFRACTION GRATING, a series of parallel straight lines spaced at equal intervals in one plane or on a concave surface. A beam of radiation after falling on such a grating, is resolved into a spectrum (*see* SPECTROSCOPY and LIGHT)

DIFFUSION, in general, a spreading out, scattering or circulation, in physics the term is applied to a special phenomenon, treated below. The word is from the Latin *diffundere* *dis-*, *asunder*, and *fundere*, to pour out.

1. **General Description**—When a few crystals of copper sulphate are placed in the bottom of a tall jar filled with water and the mixture then allowed to stand undisturbed, the blue colour of the copper ions is observed to spread slowly throughout the liquid. Initially the colour is concentrated around the crystals at the bottom of the jar, but after several weeks a faint blue coloration is seen at the surface of the water, deepening uniformly toward the bottom. Eventually (in this case after some years) a uniform solution will result.

This experiment illustrates a process which is extremely widespread in nature, whereby molecules of one substance gradually interpenetrate another substance. The phenomenon is known as (molecular) *diffusion*, we say the copper ions diffuse through the water. Diffusion is a consequence of the continuous motion of the molecules of all substances, gaseous, liquid and solid. It is the ultimate process by which irregularities in concentration of solutions disappear.

Simple cases of diffusion are easily observed qualitatively. The experiment described above is a typical example of diffusion in liquids. The diffusion of strong aniline colouring matter into the interior of gelatine is commonly seen in copying apparatus. Diffusion of gases may be shown to exist by placing a few drops of bromine in the bottom of a closed flask. The brown colour of bromine will become distributed throughout the air in the flask just as the blue of the copper became distributed throughout the liquid.

In fluid media, whether liquids or gases, the process of mixing is greatly accelerated by stirring or agitating the fluids, and liquids which might take years to mix if left to themselves can thus be mixed in a few seconds. It is necessary to distinguish carefully the effects of agitation from those of diffusion proper. Agitation brings together portions of the fluid between which considerable differences of concentration may exist. The interchange between such portions then proceeds much more rapidly. In many cases, especially in gases, the intermixing goes on until the concentration is uniform throughout. In other cases, the material remains divided into two or more regions (or phases) in each of which the relative concentration of the components is uniform, but changes in passing from one phase to the next. The passing of one or more components across the boundary between two phases is known as solution or evaporation or condensation, but the process by which the uniform distribution in each phase is set up is diffusion.

The diffusion of gases and liquids through solids is also observed (*e.g.* the passage of hydrogen through platinum). When the process is considered with reference to a membrane or partition taken as a whole, the passage of a substance from one side to the other is commonly known as "osmosis" or "transpiration" (*see* SOLUTIONS) but what occurs in the material of the membrane itself is correctly described as diffusion.

It will be shown later that ordinary diffusion due to molecular motion satisfies a partial differential equation of the form

$$\frac{\partial \rho}{\partial t} = D \frac{\partial^2 \rho}{\partial x^2}$$

where ρ is the density of the material diffusing. It can be shown that this relation is a result of the random motion of the individual molecules. The concept of diffusion has been extended on the one hand to processes which are governed by this differential equation (*e.g.* the slowing down of neutrons by collisions), and on the other to random mixing processes (*e.g.* eddy diffusion due to turbulent motion in fluids), even if the processes do not possess both properties. (In the former example given the

quantity which diffuses is not a density, in the latter the differential equation is not the same.)

Diffusion due to molecular motion is rate determining in the transfer of material across stationary layers of air or liquid. The rate of evaporation of water from a free surface (one with no blanket of gas molecules) at 20° C. is about $\frac{1}{2}$ gm per cm² per second while the diffusion controlled rate of transfer across 0.1 mm of stagnant air is 1,000 times smaller. Consequently the diffusion rate is extremely important in the design of equipment for the chemical industry, as well as in many natural processes such as evaporation of surface waters.

The process of mixing in turbulent fluids (eddy diffusion) is in many ways quite similar to molecular diffusion in quiet fluids. The motion responsible for turbulent transfer of material is that of small but appreciable quantities of fluid (eddies), unlike molecular diffusion where the thermal agitation of individual molecules is concerned. However the eddy motion is like molecular motion in that it is random with respect to the motion of the fluid as a whole. The change from molecular diffusion to eddy diffusion, which is naturally much faster, corresponds to the change from laminar or streamline flow to turbulent flow. Generally speaking the turbulence of a fluid increases with its velocity, the eddy diffusion coefficient varies with the local velocity. In the remainder of this article we shall confine our selves to the better understood phenomenon of molecular diffusion (*see* the bibliography for references to eddy diffusion) and shall assume as in our initial example that the fluids are at rest or in laminar flow.

In the next section we shall introduce the *coefficient of diffusion*, which is the ratio between the amount of material transferred across a unit of surface to the concentration gradient perpendicular to that surface. When this coefficient is known, the concentrations and transfer rates for a diffusing system are then determinable by mathematical analysis. Most of the remainder of the article concerns itself with theoretical and experimental methods for determining the diffusion coefficient. It is characteristic both of the diffusing substance and of the medium in which it diffuses.

In section 3 we examine the microscopic motion of a diffusing molecule according to kinetic theory, and find the diffusion coefficient to be proportional to the product of the molecular velocity and the average distance a molecule moves between collisions. In section 4 the analogies between material transfer (diffusion), momentum transfer (viscosity) and heat transfer (thermal conductivity) are developed, showing how the coefficients of diffusion, viscosity and thermal conduction are related. An expression for the diffusion coefficient of a pair of gases, according to Chapman and Enskog, is also given. Section 5 considers the phenomenon of diffusion in a field of force (for example a gravitational field). The field tends to create concentration inequalities by arranging the molecules into a state of lowest potential energy, while diffusion tends to iron out concentration gradients. A balance between the two effects is reached which is useful as a measure of one in terms of the other. (The point is illustrated by considering the experiments by Jean Perrin on Brownian motion, and molecular weight determination of proteins by centrifugation.)

After a brief discussion of thermal diffusion (section 6) the coefficients of diffusion of liquids in liquids, solids in solids and gases through porous solids are discussed (sections 7-9).

The wide new field of diffusion of neutrons in matter, which is so important in modern nuclear physics, is the subject of section 10. Similarities and differences with classical gas diffusion theory are pointed out. The final section gives a survey of experimental techniques for measuring coefficients of diffusion.

2. **Definitions of the Coefficient of Diffusion**—The simplest case of diffusion is that of a substance, say a gas, diffusing in the interior of a homogeneous solid medium which remains at rest, when no external forces act on the system. We may regard it as the result of experience that (1) if the density of the diffusing substance (ρ), the mass of that substance per unit volume, is everywhere the same, no diffusion takes place, and (2)

if the density of the diffusing substance is different at different points, diffusion will take place from places of greater to those of lesser density, and will not cease until the density is everywhere the same. It follows that the rate of flow of the diffusing substance at any point in any direction must depend on the density gradient at that point in that direction, $i.e.$, on the rate at which the density of the diffusing substance decreases as we move in that direction. We may define the *coefficient of diffusion* as the ratio of the total mass which flows per unit area across any small section, to the rate of decrease of the density with distance in a direction perpendicular to that section.

In the case of steady diffusion parallel to the axis of x , if p be the density of the diffusing substance, and q the mass which flows across a unit of area in a plane perpendicular to the axis of x in unit time, then the density gradient is $-dp/dx$ and the ratio of q to this is therefore the coefficient of diffusion. By what has been said this ratio remains finite, however small the actual gradient and flow may be, and it is natural to assume, at any rate as a first approximation, that it is constant as far as the quantities in question are concerned. Thus if the coefficient of diffusion be denoted by D we have $q = -D(dp/dx)$.

Further, the rate at which the quantity of substance is increasing in an element between the distances x and $x+dx$ is equal to the difference of the rates of flow in and out of the two faces, whence as in hydrodynamics, we have $dp/dt = -dq/dx$.

It follows that the equation of diffusion in this case assumes the form

$$(1) \quad \frac{\partial p}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial p}{\partial x} \right),$$

which is identical with the equations representing conduction of heat, flow of electricity and other physical phenomena. For diffusion in three dimensions we have in like manner

$$(2) \quad \frac{\partial p}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial p}{\partial x} \right) + \frac{\partial}{\partial y} \left(D \frac{\partial p}{\partial y} \right) + \frac{\partial}{\partial z} \left(D \frac{\partial p}{\partial z} \right) \\ = \text{div } D \text{ grad } p$$

The solution of such an equation can usually be expressed in terms of an expansion in an infinite series (see FOURIER SERIES, SPHERICAL HARMONICS, etc.). For a homogeneous medium we have the equation

$$(3) \quad \frac{\partial p}{\partial t} = D \nabla^2 p$$

where ∇^2 represents the Laplacian operator

In the case of a very dilute solution, the coefficient of diffusion of the dissolved substance can be defined in the same way as when the diffusion takes place in a solid, because the effects of diffusion will not have any perceptible influence on the solvent, and the latter may therefore be regarded as remaining practically at rest. But in most cases of diffusion between two fluids, both of the fluids are in motion, and hence there is far greater difficulty in determining the motion, and even in defining the coefficient of diffusion.

The experimental conditions under which diffusion is studied usually preclude such bodily motion of the whole fluid, and in other cases it is more convenient to treat such a mass motion as a separate phenomenon to be handled by the usual methods of hydrodynamics.

Accordingly a pure case of fluid diffusion is arbitrarily defined to be one in which any tendency of either component to move with excessive rapidity toward one side is offset by a current of the whole in the opposite direction, this current being of such a magnitude that the total net transfer of fluid as measured in terms of volume, is zero. The velocity of the fluid as a whole is then considered to be zero. The transfer of volume is thus balanced out by definition, but there will usually be a net transfer of mass in one direction. In defining the velocity of a diffusing fluid we are compelled to choose between a criterion in terms of volume and one in terms of mass, and the advantage seems to lie with the former.

We confine our attention to a perfect binary solution, where the volume is the sum of the volumes of the components. If N_1 and N_2 be the mole fractions of the two kinds of molecules V_1

and V_2 their mole volumes, and V the volume of one mole of mixture then

$$(4) \quad V = N_1 V_1 + N_2 V_2$$

Denoting the partial densities at any point by $\rho_1(x)$ and $\rho_2(x)$, the molecular weights by M_1 and M_2 ,

$$(5) \quad \rho_1 = \frac{N_1 M_1}{V}, \quad \rho_2 = \frac{N_2 M_2}{V}$$

Now let Γ_1 and Γ_2 denote the net volumes of each kind of molecule that pass per second across a unit area whose normal is the concentration gradient. We assume according to our discussion above that

$$(6) \quad \Gamma_1 + \Gamma_2 = 0$$

The respective mass flows are $\Gamma_1 M_1/V_1$ and $\Gamma_2 M_2/V_2$.

We define the diffusion coefficient as before by either of the equations

$$(7) \quad \frac{\Gamma_1 M_1}{V_1} = -D_1 \text{ grad } \rho_1$$

$$(8) \quad \frac{\Gamma_2 M_2}{V_2} = -D_2 \text{ grad } \rho_2$$

We notice that these equations may be written

$$(9) \quad \Gamma_1 = -D_1 \text{ grad } \frac{\rho_1 V_1}{M_1} = -D_1 \text{ grad } \frac{N_1 V_1}{V}$$

$$(10) \quad \Gamma_2 = -D_2 \text{ grad } \frac{\rho_2 V_2}{M_2} = -D_2 \text{ grad } \frac{N_2 V_2}{V}$$

and since $\Gamma_1 = -\Gamma_2$ and $\text{grad } \frac{N_1 V_1 + N_2 V_2}{V} = \text{grad } 1 = 0$

it follows that

$$(11) \quad D_1 = D_2 = D,$$

that is, the two definitions are consistent.

If we attempt to treat nonideal solutions by a similar method we are led to introduce partial molal volumes, fugacities and osmotic pressure (see SOLUTIONS). The foregoing procedure is adequate for many important cases of diffusion where the laws of perfect solutions apply, namely in gas mixtures, liquid mixtures of isotopes, dilute solutions and so on.

It is possible to consider the limiting case where a substance diffuses through itself. This is called self-diffusion. The diffusion coefficient for a pair of unlike fluids is often written D_{12} , the coefficient of self-diffusion is written D_{11} .

It will be observed from these definitions that D has the dimensions (length)² \times time = length \times velocity.

3 Diffusion as a Random Walk.—In a gas at low pressures, in which the forces between molecules are of short range, the motion of a molecule is an exceedingly irregular track consisting of short steps of varying length at sharp angles with each other.

FIG 1—PATH OF A DIFFUSING PARTICLE. EACH ANGLE MARKS THE POINT OF A COLLISION.

Each corner is the result of a collision with another molecule (fig 1). Such a path is studied in treatises on probability and is called a (three-dimensional) random walk. If a particle is placed at the origin of a set of co-ordinates at time $t=0$, it can be shown that after a large number of steps the likelihood of finding the particle within a small volume surrounding a point (x, y, z) after a time t follows the Gaussian distribution law

$$(12) \quad P(x, y, z, t) dx dy dz = \frac{1}{(2\pi R^2/3)^{3/2}} \exp(-3r^2/2R^2) dx dy dz$$

Here we have taken $r^2 = x^2 + y^2 + z^2$.

In this expression R^2 is the mean square displacement after time t for

$$(13) \quad \int P r^2 dx dy dz = R^2$$

Now the displacement after n steps is

$$(14) \quad r = r_1 + r_2 + \dots + r_n$$

and the mean square displacement is

$$(15) \quad R^2 = \overline{r^2} = \overline{r_1^2 + r_2^2 + r_3^2 + \dots + r_n^2} \\ = \overline{r_1^2 + r_2^2 + r_3^2 + \dots + r_n^2} \\ + 2(\overline{r_1 r_2} + \overline{r_1 r_3} + \overline{r_1 r_4} + \dots + \overline{r_1 r_n} \\ + \overline{r_2 r_3} + \overline{r_2 r_4} + \dots + \overline{r_2 r_n} \\ + \overline{r_3 r_4} + \dots + \overline{r_3 r_n} \\ + \dots + \overline{r_{n-1} r_n})$$

($\overline{r_1 r_2}$ reads average scalar product of vectors r_1 and r_2)

The magnitude r_i of the displacements r_i are distributed according to the law

$$(16) \quad \phi(r_i) dr_i = \frac{1}{\lambda} \exp(-r_i/\lambda) dr_i,$$

where λ is the mean free path. For simplicity let us assume all the molecules move with constant speed v . Then

$$(17) \quad r_i = \lambda v, \quad r_i^2 = 2\lambda^2 v^2$$

and if the average cosine of the angle between two successive paths (the average cosine of the scattering angle) is $\cos \theta$, it is easy to show that

$$(18) \quad \overline{r_1 r_2} = \overline{r_1 r_3} = \dots = \lambda^2 \cos \theta \\ \overline{r_1 r_2} = \overline{r_2 r_3} = \overline{r_3 r_4} = \dots = \lambda^2 (\cos \theta)^2$$

whence

$$(19) \quad R^2 = 2n\lambda^2 + (2n-2)\lambda^2 \cos \theta + (2n-4)\lambda^2 (\cos \theta)^2 + \dots$$

which for large n is closely

$$(20) \quad R^2 = \frac{2n\lambda^2}{1 - \cos \theta}$$

We also have

$$(21) \quad v t = n\lambda$$

and defining

$$(22) \quad D = \frac{1}{3} \frac{\lambda v^2}{1 - \cos \theta},$$

we have

$$(23) \quad R^2 = \frac{2v^2 \lambda^2}{1 - \cos \theta} = 6Dt$$

and finally

$$(24) \quad P(r, t) = \frac{1}{(4\pi Dt)^{3/2}} \exp(-r^2/4Dt)$$

Up to the present we have spoken of a single particle suffering displacement according to a given probability law and asked for the probability of finding this particle in some given element of volume at a later time. It is clear that we can instead imagine a very large number N of particles starting under the same initial conditions and undergoing the displacements without mutual interference. On this picture $NP(r, t)$ represents the density of particles found at (x, y, z) at time t if all the particles started from the origin at time $t=0$. This density satisfies the diffusion equation

$$(25) \quad \frac{\partial P}{\partial t} = D \nabla^2 P$$

and is in fact the solution of it representing a point source.

We have therefore shown that in the case of a point source the distribution of density by diffusion and by a random walk is the same, if we make the identification (23). It is easy to show that this parallelism holds whatever the initial distribution. Thus the phenomenon of diffusion is the result of the random motions executed by the individual particles, and the connection between the diffusion coefficient and the quantities characteristic of this motion is given by equations (22) and (23). It is useful to define the "transport mean free path" λ_t by the equation

$$(26) \quad \lambda_t = \frac{\lambda}{1 - \cos \theta}$$

λ_t is a mean free path corrected for the moderate tendency of a succeeding path to favour the direction of the preceding one. As a consequence of this persistence of velocities the dispersion and the diffusion coefficient are increased. We have then for a constant speed system

$$(27) \quad D = \frac{1}{3} \lambda_t v^2$$

4 Transport Phenomena in Gases.—Diffusion resembles the phenomena of thermal conductivity and viscosity in that it represents a tendency to uniformity of composition, while the others represent tendencies toward uniformity of temperature and mass velocity. According to the kinetic theory, the tendencies all result from the thermal motion of the molecules. This tends to equalize conditions at both ends of a free path by transporting to the further end an average

amount of momentum and energy that is characteristic of the starting point. Thus the phenomena are all known as transport phenomena. We shall give an elementary kinetic theory of the process of diffusion and derive approximate relations between the coefficients of diffusion, viscosity and thermal conductivity.

We consider a binary gas mixture at constant pressure and temperature, with composition changing along the x -axis. According to kinetic theory the number of molecules per second crossing unit area of a plane in either direction is

$$\frac{1}{4} n \bar{v}$$

where n = number of molecules per c.c.

\bar{v} = mean velocity of thermal motion.

Thus the number of molecules m_1 crossing a unit area of the plane $x=0$ in the direction of positive values of x in unit time is, if n_1 = number of molecules m_1 per c.c.

$$\frac{1}{4} n_1 \bar{v}_1$$

Here n_1 represents the mean density, not at $x=0$, but at the mean layer where the free paths of the molecules began, say at $x = -\alpha_1 \lambda_1$ where λ_1 = mean free path of molecules m_1 .

α_1 = number of the order of unity.

The number of molecules in question is thus

$$(28) \quad \frac{1}{4} \bar{v}_1 (n_1)_{x=-\alpha_1 \lambda_1} = \frac{1}{4} \bar{v}_1 (n_1 - \alpha_1 \lambda_1 \frac{dn_1}{dx})$$

Similarly the number of molecules crossing in the opposite direction is

$$(29) \quad \frac{1}{4} \bar{v}_1 (n_1)_{x=+\alpha_1 \lambda_1} = \frac{1}{4} \bar{v}_1 (n_1 + \alpha_1 \lambda_1 \frac{dn_1}{dx})$$

The net flow in the direction of positive x is therefore

$$-\frac{1}{2} \bar{v}_1 \alpha_1 \lambda_1 \frac{dn_1}{dx}$$

The diffusion coefficient (since ordinary density and number density are proportional in a gas) is therefore

$$(30) \quad D_{12} = +\frac{1}{2} \bar{v}_1 \alpha_1 \lambda_1 = +\frac{1}{2} \bar{v}_2 \alpha_2 \lambda_2$$

In a similar way we can show that the viscosity η and the thermal conductivity K are related to molecular constants by the equations

$$(31) \quad \eta = \frac{1}{2} \beta \rho \bar{v} \lambda$$

$$(32) \quad K = \frac{1}{2} \rho \gamma \bar{v} \lambda c_v$$

when ρ = density, c_v = specific heat at constant volume of 1 gram of gas and β and γ are again numbers of the order of unity.

By considering the case of self-diffusion we can get relations between D_{11} , K and η by eliminating λ . We find

$$(33) \quad D_{11} = -\left(\frac{\alpha}{\beta}\right) \frac{\eta}{\rho}$$

and also

$$(34) \quad K = \left(\frac{\gamma}{\beta}\right) \eta c_v$$

The determination of the numerical constants α , β and γ requires a deeper investigation than that given above. Factors which enter are the distribution of the molecular velocities, persistence of velocities after collisions, etc. The free path calculation of the transport coefficients, given here in an elementary form, has been largely superseded by another attack due to Chapman and Enskog. This takes account of the fact that the origin of the phenomena is a departure from the Maxwellian distribution of velocities. For details of this method the reader is referred to Chapman and Cowling, *The Mathematical Theory of Non Uniform Gases* (Cambridge University Press, 1939).

The values of the number $\rho D_{11}/\eta$ vary, depending on the law of force between the molecules. For rigid elastic spheres, $\rho D_{11}/\eta = 1.20$, for so called Maxwellian molecules, which are centres of force repelling proportionately to the inverse fifth power of the distance, $\rho D_{11}/\eta = 1.54$.

Experimental results give $\rho D_{11}/\eta$ between 1.3 and 1.5, in reasonable agreement with theory (Chapman and Cowling, p. 251).

The expression for $K/\eta c_v$ was shown by Eucken to be

$$(35) \quad K/\eta c_v = \frac{1}{4} \left(\frac{5}{2} \epsilon - \frac{5}{2} \right)$$

where ϵ = specific heat at constant pressure of a gram of gas. The agreement with experiment is generally good (Chapman and Cowling, p. 241). These relations enable us to estimate self-diffusion coefficients if either viscosity or thermal data are available. (It should be remarked that a similar set of relations is valid for transfer phenomena in eddy diffusion.)

The kinetic theory expression for the diffusion coefficient of a pair of gases at absolute temperature T is

$$(36) \quad D_{12} = (1 + \epsilon_{12}) \frac{1}{8} \sqrt{\frac{T}{\pi}} \frac{1}{n S_{12}} \left(\frac{m_1 + m_2}{m_1 m_2} T \right)^{1/2}$$

Here S_d is an equivalent mutual cross section of the two kinds of molecules for diffusion, m_1 and m_2 are the molecular masses, $k = \text{Boltzmann's constant} = 3.81 \times 10^{-14}$ in c.g.s. units, and ϵ_1 is a small correction term of the order of a few hundredths.

For hard spheres of diameters σ_1 and σ_2

$$(37) \quad S_d = \frac{\pi(\sigma_1 + \sigma_2)^2}{4}$$

It will be observed that (36) is of the same form as (27) which was derived for a constant speed gas, as $\frac{1}{\pi S_d}$ is a free path and

$\sqrt{\frac{m_1 + m_2}{m_1 m_2}} k T$ has units of velocity. The two expressions agree very closely when m_2 and m_1 are very much larger than m_1 and m_1 , which are conditions which give physical reality to section 3.

From (36), D_{12} varies inversely as the pressure, and since for constant pressure n varies as $1/T$, D_{12} varies ostensibly as $T^{3/2}$. Actually S_d decreases slightly with the mean velocity of the molecular collisions, and thus D_{12} is found to vary as a slightly higher power of T , between $n^{1/2}$ and $n^{3/4}$.

D_{12} for a pair of light gases like nitrogen + oxygen is about 0.2 cm²/sec. at room temperature.

5 Diffusion in a Field of Force—We shall consider either a mixture of two gases, or a dilute solution or suspension of a high molecular weight compound in a low molecular weight solvent, such as water. Then if u_1, u_2 are the potential energies of the two kinds of molecules in the force field, the equilibrium distribution is given by Boltzmann's equations

$$(38) \quad \begin{aligned} n_1 &= n_{10} \exp -u_1/kT \\ n_2 &= n_{20} \exp -u_2/kT \end{aligned}$$

n_1, n_2 are the number densities, n_{10} and n_{20} are the number densities at some reference point at which the zero of energy is taken. This distribution is a dynamic equilibrium between the force acting on the molecules, which tends to move them in the direction of the force, and the process of diffusion, which tends to erase all concentration gradients and so creates a current opposite to the force. The diffusion current is always

$$-D \text{ grad } n_1$$

and at equilibrium is just balanced by the current created by the field which must therefore be

$$(39) \quad \begin{aligned} n_1 v_1 &= +D \text{ grad } n_{10} \exp -u_1/kT \\ &= \frac{D n_1 F_1}{kT} \end{aligned}$$

where $F_1 = -\text{grad } u_1$ is the force on the molecule.

When the system is not in the equilibrium state the two contrary tendencies are still working, although no longer in balance. The equation of continuity is then (in the absence of other currents)

$$(40) \quad \frac{\partial n_1}{\partial t} + \text{div} [n_1 v_1 - D \text{ grad } n_1] = 0$$

and a similar equation holds for n_2 .

If we have the case of a dilute solution of a large molecule of mass m_1 in a solvent, Stokes' law tells us that

$$(41) \quad v_1 = \frac{F_1}{6\pi\eta a}$$

when η = viscosity of the liquid, and a the radius of the molecule. Thus

$$(42) \quad D = \frac{v_1 kT}{F_1} = \frac{kT}{6\pi\eta a}$$

a relation due to Albert Einstein in a gravitational field

$$(43) \quad F_1 = (m_1 - \rho V_1)g$$

where ρ is the density of the solvent, V_1 the volume of the large molecule and g the gravitational acceleration.

If we make separate observations of v_1 (the sedimentation velocity) and D (see below, section 17), we can determine

$$(44) \quad F_1 = \frac{v_1 kT}{D}$$

a and hence V_1 , and so finally m_1 . This method of determining the molecular weight of large molecules is widely used in biochemistry. The gravitational field g is usually supplied by an ultracentrifuge, which gives fields strong enough to make the method useful on molecular weights down to 10,000.

Perkin, in his classical investigation of Brownian movement, verified by direct observation almost all the theoretical relations used in this article. He used a suspension of particles which were visible to the ultramicroscope, yet so small that their velocity of thermal agitation was sufficient to give visible displacements in short periods of time. He verified successively the Boltzmann distribution law, the relation (23) which demands that the mean square displacement be proportional to time and the Gaussian distribution of displacements (12). Using the value of D calculated from (21) he used (42) where

T, η and a were known as a determining equation for the Boltzmann constant. The rate of the gas constant R to k is the Avogadro number (number of molecules per gram mole) he found 6.8×10^{23} . (The best present value is 6.02×10^{23} .) The ensemble of experiments was a striking confirmation of the kinetic theory.

The two different distributions (38) obviously offer the possibility of separating a mixture of gases in a force field. The rate at which the field can transfer material is, according to (39), determined by the diffusion rate which therefore is the limiting factor in such separations (See *Isotope Separation of Isotopes*).

6 Thermal Diffusion—A close study of the properties of fluid mixtures shows that if a temperature gradient exists, a gradient of composition will also be established. The concentration gradient thus set up is opposed by the ordinary process of diffusion, just as the concentration gradient set up in a field of force is opposed. The steady state is characterized by the equation

$$(45) \quad D_{12} \text{ grad} \left(\frac{n_1 - n_2}{n_1 + n_2} \right) = \frac{D_T}{T} \text{ grad } T$$

where D_T is defined as the coefficient of thermal diffusion.

This phenomenon, whose existence was unsuspected until 1911 and not demonstrated experimentally until 1916, aroused unusual interest after 1939 when Klaus Clusius and G. Dickel found a use for it as the basis of an exceptionally simple device for separating isotopes. Since then the effect has been observed on many isotopic mixtures, liquid as well as gaseous. One of the methods used for separating U^{235} from U^{238} for the release of atomic energy was thermal diffusion on liquid UF_6 . For further details on this interesting phenomenon, see references in the bibliography.

7 Diffusion in Liquids—Corresponding to our limited understanding of the liquid state, our knowledge of the process of diffusion in liquids is much less than in gases. Although diffusion in liquids is qualitatively the same, and the interpretation of the diffusion coefficient as proportional to the mean square displacement per unit time is unchanged, we have much less success in a priori quantitative estimation of D .

A suggestive interpretation of the process of diffusion in liquids, based on the theory of absolute reaction rates, was developed by Henry Eyring. He found the following equation to be given by the equation

$$(46) \quad D = \lambda \frac{kT}{h} \exp -\Delta F/kT$$

In this equation λ is the distance between two successive lattice positions of the diffusing molecule, ΔF is the "activation energy" which must be acquired by a molecule to pass over the energy barrier between the two lattice points, and

$$\frac{kT}{h} \exp -\Delta F/kT$$

is the rate at which the molecule "reacts" in such a process (h = Planck's constant).

In terms of the viscosity η , by the same theory, the self-diffusion coefficient is found to be

$$(47) \quad D_{11} = \frac{kT}{\lambda \eta}$$

which may be compared with the Stokes-Einstein equation (42) for a very large molecule diffusing in a solvent of viscosity η . By qualitative arguments (47) is extended to diffusion in binary mixtures

$$(48) \quad D_{12} = \frac{kT}{2b\eta a}$$

Here η is the viscosity of the smaller molecules, a the radius of the larger molecules and b a factor which varies between $3/4$ for very large spherical molecules diffusing in small molecules and $1/2$ for self-diffusion (when $\lambda = 2a$).

Generally diffusion coefficients in a liquid are of the order of $1 \text{ cm}^2/\text{day}$, i.e. 10^{-6} times as small as in gases. The transport by diffusion across a unit distance, for a given concentration difference, is proportional to $D \times \text{density}$. Since the density of liquids is only 10^3 times that of gases, it follows that molecular diffusion is between 10 and 100 times more efficient in the gas phase.

8 Diffusion in Solids—There are many types of diffusion in and through solids, including true solid-solid atomic diffusion (e.g. gold in lead), liquid-solid (water through semipermeable membranes or body tissues), gas-solid (hydrogen through platinum) and gaseous solid (gases through clay pipes). In this section we shall consider only diffusion in nonporous solids, diffusion through porous solids is treated in the next section.

Two mechanisms are conceivable for diffusion of atoms A in a nonporous crystalline solid AB . The A atoms may diffuse individually through interstices in the lattice AB , or the diffusion may take place with the help of vacancies, the atoms moving into vacant adjacent sites. We have seen that $D = R^2/6t$, where R^2 is the mean square displacement of a diffusing atom in a time t . Now by symmetry $R^2 = 3\bar{x}^2$ if \bar{x}^2 is the mean square displacement in a given direction. Hence $D = \bar{x}^2/2t$. Then if λ is the distance between atomic planes, and ν the frequency with which atoms jump from one plane to the next, it follows that

$$(49) \quad D = \frac{1}{2} \nu \lambda^2$$

ν equals the fraction of vacancies or interstitial atoms, times the probability that an atom will jump into a vacancy or from one interstitial position to another. Since both of these factors have the form $c \exp(-\epsilon/kT)$ we have finally

$$(50) \quad D = \nu \lambda^2 \exp(-\epsilon/kT)$$

much as in the case of liquids

ν_0 is the jump frequency at temperatures so high that $kT \gg \epsilon$ in metals values of about 10^{13} per second are common. ϵ ranges from about $\frac{1}{2}$ to 2 electron volts. λ is of the order of a few angstroms. At ordinary temperatures kT is about $\frac{1}{40}$ electron volt. A typical value of D in a metal might be

$$(\epsilon = 1 \text{ ev, } T = 325^\circ \text{ C})$$

$$D \sim 10^{-13} \cdot 10^{-18} e^{-20} \sim 2 \times 10^{-31} \text{ sec}^{-1} \cdot 6 \times 10^{-4} \text{ cm}^2/\text{year}$$

The 1000 mean square displacement in a year is about three-tenths of a millimeter

9 Diffusion of Gases Through Porous Solids—In the passage of gases through porous solids, the type of diffusion which occurs depends on the pressure of the gas and the pore size. At atmospheric pressure and with fairly large pores (e.g. coarse unglazed pottery) the principal function of the solid is to inhibit hydrodynamic flow, the diffusion that takes place is largely ordinary molecular diffusion of one gas through another. At pressures so low (or pore sizes so small) that the mean free path of a molecule is large compared with the pore size, a phenomenon known as free molecule diffusion takes place. A molecule in one of the pores now makes many collisions with the walls for one collision with another molecule. The mean free path in a long cylindrical pore is just the diameter of the tube (2a) and the diffusion coefficient for a molecule of mass m and mean speed \bar{v} is simply

$$(51) \quad D = \frac{2}{3} \bar{v} a$$

As \bar{v} is proportional to $1/\sqrt{m}$ by the law of equipartition of energy, it follows that the diffusion coefficients of different gases in free molecule flow are inversely proportional to the square roots of their molecular weights. This is Graham's law (1829-1861).

The flow (in grams/second) through a cylindrical capillary of length l , with a pressure difference Δp maintained across it, is similarly

$$(52) \quad \frac{d^2 p}{dx^2} = \frac{4}{3} \sqrt{\frac{2\pi m}{kT}} \frac{a^2}{l} \Delta p$$

on introducing (51) for D and $\bar{v} = 2\sqrt{kT/m}$ for a Maxwellian gas. Equation (52) was first found by Martin Knudsen (1909).

On passing a mixture of two gases at low pressure through a porous solid, an alteration of the composition of the mixture occurs, as each gas flows through independently at a rate determined by its own diffusion coefficient. It is easy to show from (52) that if the ratio of partial pressures on the high pressure side of the porous barrier is p_1/p_2 , on the low pressure side of the ratio is $p_1\sqrt{m_2}/p_2\sqrt{m_1}$, provided the pores are small compared with the mean free path on the high pressure side, and also that the low pressure is much smaller than the high.

This method of separating gases was employed by Baron Rayleigh and Sir William Ramsay in their classical work on the composition of the gases in the atmosphere. It was, however, little more than a laboratory curiosity until 1945 when the plant gas diffusion plant of

the United States Atomic Energy Commission was built at the University of Chicago. This plant was designed to separate the isotopes of uranium and thorium by the diffusion of their hexafluoride compounds through a porous barrier. The principle of the plant is based on the fact that the lighter isotope of uranium, ^{235}U , diffuses slightly faster than the heavier isotope, ^{238}U , through a porous barrier. The plant consists of a series of stages, each of which is a diffusion cell. In each stage, a mixture of the two isotopes is passed through a porous barrier, and the lighter isotope is separated from the heavier isotope. The separated isotopes are then collected and used for various purposes.

11 Diffusion of Thermal Neutrons in an Absorbing Medium—In the case of thermal neutrons, the diffusion coefficient is not a constant, but varies with the energy of the neutrons. This is because the cross-section for absorption of neutrons varies with energy. The diffusion of thermal neutrons through matter has been very intensively studied in connection with this process.

The theory of neutron diffusion presents many difficulties which are not shown in ordinary gas diffusion. Neutrons, because of their non-electrical nature, find matter largely empty. To be deflected they must collide with a nucleus, which is only a minute fraction of the volume of an atom. The mean free paths of neutrons diffusing through solid matter are consequently about 1,000,000 times greater than the mean free path in gases at ordinary pressures (1 cm as opposed to 10^{-8} cm). While boundary effects, which vanish a few mean free paths away from the boundary itself are usually negligible in gas diffusion, they are significant for neutrons. An even more

fundamental complication is that neutrons are captured on collision as well as scattered.

As a first approximation we may take account of the absorption of the medium by adding an extra term to the diffusion equation

$$(53) \quad \frac{\partial n}{\partial t} = D \nabla^2 n - \frac{v}{\lambda_a} n$$

In (53), n is the neutron density, v the speed, λ_a the mean free path for absorption and D the diffusion coefficient from (27). λ_a/v is the "lifetime" of a neutron the term $n/\lambda_a v$ is the number of neutrons per second per cc which are captured. Taking the steady state, $\frac{\partial n}{\partial t} = 0$, and a one dimensional problem, (53) reduces to

$$(54) \quad D \frac{d^2 n}{dx^2} - \frac{v n}{\lambda_a} = 0$$

which has solutions of the form $\exp \pm \sqrt{\kappa} L$. L is known as the diffusion length and according to (54) and (27)

$$(55) \quad L^2 = \frac{\lambda_a D}{v} = \frac{1}{3} \lambda_a \lambda_t$$

which is an expression due to Enrico Fermi.

A more exact theory shows that equation (54) is correct provided D is interpreted as

$$(56) \quad D = \frac{v L^2}{\lambda_a} \frac{1}{1 - \cos \theta}$$

and the new fundamental quantity L is related to λ_a , the mean free path for scattering, and λ_t the mean free path for scattering and absorption

$$(57) \quad \frac{1}{\lambda} = \frac{1}{\lambda_s} + \frac{1}{\lambda_a}$$

by the equation

$$(58) \quad \frac{\lambda}{L} = \tanh \frac{\lambda_s}{L}$$

Diffusion lengths in paraffin, graphite, water and other common materials for slowing down fast neutrons run between 10 and 50 cm.

The boundary conditions to (54) are often expressed in terms of the reflection coefficient or albedo, which is the ratio of the number of neutrons reflected by an outside medium to the number of neutrons leaving the boundary outward bound.

The process of the slowing down of fast neutrons to thermal energies may also be expressed as a form of diffusion.

12 Measurement of Diffusion Coefficients—As we have seen in the preceding sections, the topic diffusion covers an extremely varied set of phenomena. Quantitatively, diffusion coefficients range from greater than $10^2 \text{ cm}^2/\text{sec}$ (neutrons) to less than $10^{-14} \text{ cm}^2/\text{sec}$ (atoms in metals). Corresponding to this diversity each measurement of diffusion offers its own particular problems and opportunities and requires its own special techniques. For example, in measurements of diffusion in liquids, convection is very troublesome, while in solids the problem is principally the minuteness of the effect over reasonable periods of time. The analytical methods whereby the concentration changes are measured are also most numerous. The concentration of neutrons is determined by the radioactivity which they induce in thin metal foils used as detectors. The concentration in gases or solutions may be found by a chemical analysis, by the refractometer, polarimetrically or by the mass spectrometer. The concentration in thin slices of metal may be determined spectrographically by X ray diffraction by radioactive indicators or by chemical analysis.

There are, however, some features which are common to all diffusion experiments. Measurements of diffusion coefficients are either based on the transport equation which defines D

$$(59) \quad q = -D \frac{dp}{dx}$$

where q is the flux in grams/sec/cm², or on an analysis of the concentration distribution which is a solution of the equation

$$(60) \quad \frac{\partial p}{\partial t} = \text{div } D \text{ grad } p$$

In a typical experiment of the first kind, a water solution of glucose is placed in a cell, one wall of which is a porous plate. Pure water is kept flowing on the other side of the plate. The porous plate serves to immobilize the water. Diffusion of glucose in water takes place within it. If A be the effective area of the plate (determined by an experiment with a reference substance) and l its thickness, c the concentration of the glucose solution and Q the loss of glucose in time t , then

$$(61) \quad D = \frac{Ql}{Atc}$$

Any convenient way of determining the glucose concentration may be used for example densimetric measurements. Obvious modifications of this method make it suitable for measuring diffusion of gases through solids.

An example of the measurement of a diffusion coefficient by analysis

ney through the alimentary canal, where it comes into contact with the digestive juices and thus undergoes chemical disintegration, the products being finally absorbed. The three chief functions of the digestive tract are (1) propulsion of food along the tract, (2) secretion of digestive juices by glands which are connected with the tract by means of ducts or situated in the walls of the tract, (3) absorption of the final products of digestion.

Salivary Secretion—The food undergoes its first change while in the mouth, it is broken up into small pieces during the process of mastication, and is well mixed with the first digestive juice, the saliva. The normal secretion of saliva can best be studied in animals in which the natural opening of one of the salivary glands has been surgically transplanted from the inside skin of the mouth to the outside, so that the saliva flows from the gland through the diverted duct to the chin or cheek of the animal. As a result of this harmless operation, the saliva can easily be collected, measured and analyzed. This operation is known as the establishment of a salivary fistula. The results have been compared with observations on man obtained in cases where a fistula became established as the result of accidental injury. The salivary glands must be divided into two groups according to their structure and the composition of the secretion. The first group consists of the mucous glands (submaxillary and sublingual glands) which secrete viscid saliva, rich in the glucoprotein mucin. The second group comprise the serous glands (parotid gland), the juice of which contains no mucin and is therefore watery, it contains, however, some other proteins mainly of the globulin type. In man and certain other animals, both sets of glands secrete the enzyme ptyalin. Before and after the periods of intake of food, the glands are at rest, for the moisture of the mouth depends chiefly on the continuous secretion of small glands covering the mucous membrane, and not on the secretion of the salivary glands.

Function and Composition of Saliva—On the administration of food, all the salivary glands begin to secrete, the amount of secretion being proportional to the length of time the food remains in the mouth. It is, however, not only food substances which evoke secretion. This power is also possessed by certain chemical substances which often are not swallowed but ejected from the mouth, as for instance acids, alkalis, salts and various irritants such as pepper, mustard, etc., secretion is even evoked by some substances whose irritant nature is due to purely mechanical properties, as is the case with fine sand and certain powders. It is obvious that many of these irritants play a considerable role in our daily menu, though they cannot be regarded as nutritive substances. The main function of saliva is to soften and lubricate, in order to make the food able to pass through the comparatively narrow oesophagus tube to the stomach. In the case of irritants, the purpose of saliva is to dilute them, and to protect the mucous membrane of the mouth by covering it with a layer of viscid mucin. The primary function of the saliva is therefore physical, but in man and those animals whose saliva contains ptyalin, there is the further function of assisting in the chemical decomposition of the higher carbohydrates.

The composition of saliva secreted on administration of the two classes of stimuli (food and irritants) is very different. When food is given, the mucous glands secrete a viscid saliva, rich in mucin, but when irritants are administered, the secretion contains hardly any mucin. This difference in viscosity can be demonstrated by observing the length of time taken by different samples of saliva to flow through a capillary tube, and comparing the rates with that of water. For instance, in one experiment, 1 cc of water took 6 seconds to pass through the viscosimeter,

1 cc of saliva obtained on introduction into the mouth of 0.5% HCl took 8 seconds, of an emulsion of mustard 9 seconds, of 2.5% NaCl 9 seconds, while 1 cc of saliva obtained on administration of bread took 95 seconds, of meat 175 seconds, of milk 231 seconds and of dried powdered meat 255 seconds. On determining the organic and inorganic constituents of the saliva, it was found that the "alimentary" saliva from the submaxillary gland contained about 0.99% of organic matter, and about 0.4% of inorganic, while that secreted after administration of irritants contained only about 0.1-0.2% of organic matter, and about the same percentage of inorganic matter, namely from 0.35-0.45%. These peculiar differences in the composition of saliva are exhibited only by the mucous glands. The parotid saliva varies little, and with both types of substance has approximately the same composition (0.9-1.0% of organic and 0.35-0.48% of inorganic matter). The organic substances are proteins and ptyalin, and the inorganic are chiefly potassium chloride, which appears in considerably larger quantities than in the blood, sodium chloride, sodium bicarbonate and potassium sulphocyanide.

Mechanism of Salivary Secretion—The amount of saliva secreted depends on the length of time any particular substance remains in the mouth, and also on the extent to which the substance can mechanically or chemically stimulate the mucous membrane of the mouth. Dry substances always evoke a far more copious secretion than liquids. The results of an actual set of observations will serve as an illustration. The following substances were administered for one minute each: Dry bread and the same soaked in water, the resulting secretion measured 3.9 cc and 1.4 cc respectively, with dry meat powder and the same soaked in water, the secretions were 4.5 cc and 1.9 cc respectively, and with dry sand and the same soaked in water, 2.8 cc and 0.4 cc. It is obvious that the purely mechanical stimulation caused by the various substances is enough to bring about secretion. Pure water at body temperature evokes no secretion, but saliva is secreted on administration of both hot and cold water, and in each case the composition is the same as that obtained on administration of irritants. The concentration of the chemical stimuli is also of considerable importance. For instance, on administering HCl in concentrations of 0.1, 0.2, 0.3, 0.4 and 0.5% for one minute the total secretion was in one experiment 5.2, 7.4, 8.1, 9.2 and 9.5 cc respectively.

The movements of mastication do not evoke salivary secretion in the absence of the higher parts of the central nervous system, the well known effect of smell and sight of food is in this case also absent. The secretory effect of these stimuli is the result of association, and will be discussed in the section on conditioned reflexes. The mechanism of salivary secretion is based on a reflex act. Foodstuffs or irritants, in virtue of their chemical or mechanical nature, stimulate the peripheral nerve endings of the sensory nerves of the mouth and tongue, namely the lingual and the glossopharyngeal nerves. The nervous impulse passes along these nerves to the salivary centre in the medulla, and is there transmitted by the efferent (secretory) nerves to the corresponding salivary glands. The higher centres are not necessary for the normal reflex salivary secretion. In dogs in which the brain has been destroyed above the medulla, all the characteristics of the salivary secretion are preserved, moreover, the composition and amount of the secretion depend on the nature of the stimulus in the usual way. After injury to the medulla or after section of both sensory nerves of the mouth, secretion cannot be evoked either by the act of eating, or by irritants.

Nerve Connections—The chief secretory fibres of the two mucous glands were discovered by Ludwig in 1851. They run in the chorda tympani, which is a branch of the facial nerve. The secretory fibres of the parotid gland pass along the glossopharyngeal nerve. Electrical stimulation of these nerves evokes an immediate and copious secretion from the corresponding glands, the rate of secretion being proportional to the strength of the stimulation. All the salivary glands also receive a nerve supply from the sympathetic system, via the cervical sympathetic nerve. The saliva obtained from the mucous glands after stimulation of the cerebral nerves of the dog is more copious and less viscid than

FIG. 1—DIAGRAM SHOWING POSITION OF SOFT PALATE (TIGERSTEDT).
2. During rest. 2. During the act of swallowing.

that obtained after stimulation of the sympathetic nerve

Stimulation of the cerebral nerves produces a very considerable vasodilation and therefore increases the blood supply to the gland, while stimulation of the sympathetic nerves produces vasoconstriction to the point of almost arresting the circulation. The correlation formerly drawn was that the extent of secretion and the composition of the saliva were dependent on changes in the blood supply accompanying the stimulation of the corresponding nerves. But it is now generally accepted that the composition of the secretion depends little if at all on the blood flow. At any rate, the saliva does not become more concentrated if on stimulating the cerebral nerve the blood flow is reduced to its original level nor does it become more dilute if the blood flow is artificially increased. The differences in the composition of the saliva and the amount secreted in the normal animal during administration of various substances is certainly not dependent on changes in blood flow (as proved by direct measurements), neither is it dependent on the presence of the sympathetic fibres. After section of all the sympathetic connections, the secretion remains viscid in the case of food, and fluid in the case of irritants.

The part played by the sympathetic nerves in normal secretion is not definitely known. After section of the latter, the secretion hardly changes, while after section of the cerebral nerve it ceases. Artificial stimulation of the sympathetic nerve, however, produces a slight flow of saliva, and causes definite histological changes in the gland. Besides the secretory and vasomotor fibres, the sympathetic nerve contains fibres which stimulate some contractile elements around the secretory cells, and thus help to empty the gland of the viscid juice. The cerebral nerves have no such fibres. The secretory nerve endings of the cerebral salivary nerves are completely paralysed by atropine while the vasodilator nerves are left intact—a further proof that secretion is not due to vasodilation.

The Metabolism of the Gland.—The activity of the glands is accompanied by increased metabolism, and the consumption of oxygen and blood sugar may be increased during secretion tenfold. The organic substances and ptyalin which are secreted by the gland are derived from the stores laid down by the gland during the period of rest, and the inorganic substances are derived, together with the water, from the blood. In protracted secretion, as the stores are depleted, the saliva becomes progressively poorer in organic substances, and finally contains only inorganic substances and some urea. A gland can however excrete as much as one third of its total nitrogen, showing that the store of organic substances is considerable. As regards water, a gland may be able to secrete over 100 times its own weight in the course of a few hours. The rate of secretion from all the salivary glands in man may be roughly estimated at about one litre.

Secretion is not a filtration of water from the blood through the gland with a certain amount of stored substances, but is an active process, the energy for which is derived from oxidations within the gland itself. This is most conclusively proved by the fact that secretion ceases in the absence of oxygen.

The secretion of saliva is under the control of the cerebral and sympathetic nerves, and is also influenced by local factors such as the presence of food in the mouth.

Deglutition.—The act of deglutition is a complex one, involving the contraction of the tongue, the pharynx, and the oesophagus. The tongue, assisted by the surrounding muscles (chiefly mylohyoid, also styloglossus, palato-glossus) The contraction of the palatoglossus closes the isthmus faucium, thus preventing the return of food towards the mouth. In the pharynx, the food passes a region common to the respiratory and digestive system, but the respiratory passages are temporarily closed. The act of deglutition is impossible unless the larynx is free to move. The bolus is now shot rapidly into the region of the medium and lower constrictors of the pharynx, and then into the oesophagus. Liquids and semi-solids quickly pass down the oesophagus to its cardiac end. Here the passage becomes less rapid, the fluid escaping slowly in a narrow stream into the stomach. The average time for a complete act of deglutition is about 6 seconds for liquids and semi solids, but dry food substances may take as long as 15 minutes to reach the stomach. The propulsion of liquids is mainly due to the movement of the back of the tongue, but that of solids is due to the contraction of the constrictors of the pharynx and the oesophageal muscles, which slowly push the food towards the stomach.

The passage of food along the oesophagus is assisted by a reflex inhibition of the wall, which is succeeded by a contraction. In every complete act of deglutition there are thus two waves which pass along the oesophagus, one of relaxation and the other of contraction. If however several deglutitions follow one another at short intervals, the wave of contraction has no time to develop, and the succeeding waves of relaxation fuse with one another, thus causing a relaxation of the oesophagus along its whole length. The tube therefore becomes an open passage through which large amounts of liquid can pass into the stomach by mere force of gravity. When swallowing stops, a strong wave of contraction develops. These waves of relaxation and contraction are due to a reflex, and they are not arrested by complete transverse section of the oesophagus, but are stopped by section of its nerves.

There is an important interdependence between respiration and deglutition, for every act of deglutition inhibits a respiratory movement. In the absence of this correlation, food might easily slip through the open respiratory passages into the trachea, which may actually happen in cases of paralysis of the laryngeal muscles. The arrest of respiration may last as long as 6 seconds. That deglutition is impossible in the absence of a bolus is shown by the fact that a man with an empty mouth can perform only four or five swallowings in rapid succession, after which swallowing becomes impossible for a time. The first acts of deglutition were possible because of the presence of saliva in the mouth after rinsing the mouth with a weak solution of atropine even a single deglutition is impossible without taking some liquid.

Gastric Secretion.—Anatomically, the stomach is divided into the fundal or cardiac portion and the pylorus. Physiologically, the pylorus of the carnivorous animal resembles the intestinal tract proper rather than the rest of the stomach. As the result of an accidental wound in the stomach of a Canadian hunter, a permanent gastric fistula was established, and Beaumont was able, in 1834, to observe directly the movements and secretion of the stomach. The effects of administering food. In 1843, Bassow, an established artificial gastric fistulae in dogs, and time various operations on the stomach have been performed in physiological experimentation.

The period of digestion, the gastric glands are at work, the juice being secreted by the superficial epithelial cells about 5 minutes of the intake of food, the gastric secretion. The secretion gradually increases in rate, and the rate of secretion outlasts the actual period of eating. The rate of secretion—In order to determine whether it is the act of deglutition or the entry of food into the stomach that brings about the secretion, Pavlov performed the following operation. In a dog in which a gastric fistula had been established, he made a small incision in the skin of the neck, and sutured the end of the oesophagus in the neck, and sutured the end of the oesophagus and could be eaten again. The dog was of course to be fed either through the lower end of the oesophagus or through the gastric fistula. Animals operated on in this manner live as long as they would normally, and

experience no discomfort whatever. When these animals are fed through the mouth (sham feeding), the gastric glands begin to secrete, exactly in the same manner and after the same latent period as in the normal act of eating. The secretion lasts for hours so long as sham feeding is continued, and after its termination the secretion gradually declines, and finally ceases within 10-20 minutes. The conclusion from these experiments is that the onset and the maintenance of the secretion is a reflex which, like that of the salivary secretion, originates in the mouth. The afferent nerves for this reflex are the same as for the salivary secretion, while the secretory fibres run along the vagus nerve. The centre for gastric secretion lies in the medulla. This reflex secretion does not involve the co-operation of the higher nervous centres, and is readily obtained in dogs whose entire fore-brain has been removed. After section of both vagi, the reflex cannot be evoked, just as happens in the case of the salivary glands after section of their respective secretory nerves.

The rate of gastric secretion, the amount of juice secreted, and the composition of the juice (see NUTRITION) vary little with different food substances. The juice obtained after administration of fats is deficient in pepsin. The experiments with sham feeding were repeated and confirmed in the case of a man in whom a gastric fistula had to be established on account of stricture of the oesophagus. The amount of juice secreted by an average sized dog may be as much as 200 cc. after half an hour of sham feeding, but the secretion may vary considerably.

Part Played by the Higher Centres.—Like the amount of saliva, the amount of gastric juice secreted is largely dependent on appetite. A hungry animal may give, in the same period of time, 5 times more juice than an animal which recently has been fed. It is not only contact with the mucous membrane of the mouth that evokes the reflex, but also the sight and smell of food, and in fact all those stimuli which the animal associates with food. These effects are entirely dependent on conditioned reflexes (see on the higher centres), which in ordinary life play an extremely important part in regulating the activities of all the systems of animals and man, amongst these activities are those of the alimentary glands, which stand in close relation to the central nervous system. Administration of tasteless food, monotony in food, and gross irregularity in the time of feeding will all affect gastric secretion. If the intake of food is too rapid, the secretion will not have time to develop to its maximum, and the food will remain undigested for a considerable time. It is known that the amount of juice secreted, and therefore the digestive and nutritive properties of the food, depend in the long run not so much on the weight or caloric value of the food as on how we eat it, how it is prepared and served, and how we prepare ourselves and concentrate on its intake. However, if man's nutrition depended entirely on his wisdom, only a few would survive, and the organism has, in the case of gastric secretion, a mechanism which is controlled independently not only of the higher centres, but also of the medullary reflex mechanism.

The Chemical Mechanism.—This mechanism was also discovered by Pavlov. If certain food substances are introduced through a fistula directly into the stomach, secretion of the gastric juice ensues. This secretion is independent of the nervous system, and can be obtained in a stomach after section of all its nerves. The chemical mechanism of gastric secretion is a reflex which, like that of the salivary secretion, originates in the mouth. The afferent nerves for this reflex are the same as for the salivary secretion, while the secretory fibres run along the vagus nerve. The centre for gastric secretion lies in the medulla. This reflex secretion does not involve the co-operation of the higher nervous centres, and is readily obtained in dogs whose entire fore-brain has been removed. After section of both vagi, the reflex cannot be evoked, just as happens in the case of the salivary glands after section of their respective secretory nerves.

As regards the nature of the substances producing secretion on

entry into the stomach, it is known that unchanged food substances, whether carbohydrates, fats or proteins, are unable to produce this secretion. The secretion is however evoked by the presence of the products of the digestion of proteins (peptones, albumoses) and of fats (fatty acids, soaps). Substances which may be extracted from meat and vegetables on boiling (probably the albumoses) also evoke the secretion if they are introduced directly into the stomach. A most illustrative example is provided

FROM STARLING: PRINCIPLES OF HUMAN PHYSIOLOGY (IN 8 VOLUMES)

FIG. 2.—SHADOW SKETCHES OF THE OUTLINES OF A CAT'S STOMACH, OBTAINED BY MEANS OF X-RAY ILLUMINATION IMMEDIATELY AFTER A MEAL CONTAINING BISMUTH SALTS FED AT 11, 12, 2, 3, 30 AND 430

by the following experiment. Direct introduction of raw meat into the main part of the stomach, after a latent period of about 15 minutes, brought about a considerable secretion from the isolated pouch, a similar introduction of an equal quantity of meat which had been boiled for several hours produced no secretion at all, but the water in which the meat had been boiled caused the same secretion as raw meat. Boiled meat which had been subjected to gastric digestion *in vitro* produced a very large secretion. The experiment is practically duplicated with vegetables, but on a smaller scale, except that the peptic digestion of the thoroughly boiled vegetables makes no appreciable difference.

There are however proteins which do not yield any extractive substances which are capable of stimulating gastric secretion (for instance egg white), though on digesting them with gastric juice they acquire strong stimulating properties. In general, we can say that extractive substances from proteins, the products of the digestion of proteins but not proteins themselves, and the products of the digestion of fats but not fats themselves bring about gastric secretion when introduced into the stomach, and this secretion is not under the control of the nervous system.

Two Phases.—The whole gastric secretion may thus be divided into two phases, the first **reflex phase** (through the vagus nerve), and the second or **chemical phase**. The first phase is by far the most important—it starts the digestion of proteins, and thus leads to the production of those chemical substances which will further stimulate the secretion of gastric juice. But how much more than mere custom there is in the taking of soup before a meal, in this way we administer to the stomach extractive substances derived from meat or vegetables, and thus ensure that, even in the absence of appetite, our food will meet with some gastric juice in the stomach.

The mechanism underlying the chemical phase of secretion is not yet clear. It is, however, known that the products of digestion of proteins, etc., need not come into contact with the fundal part of the stomach at all, they must, however, come into contact with the mucous membrane of the pylorus, and this is the way in which they produce their effect. There is much evidence for the view that, under the action of these stimulations, a substance (generally called gastrin [Edkins]) is liberated by the pylorus into the blood, the blood then brings this substance to the fundal glands and stimulates them to secrete the juice. That the stimulus is carried by the blood stream can be regarded as proved, at least in cases of transplantation of parts of the stomach to the thigh and chest of the animal, for extractive substances on introduction to the main stomach evoke secretion in the transplanted part.

Besides the two phases of gastric secretion, there are no other methods of evoking secretion, and in any given case the amount of gastric juice secreted, in a complete act of eating, is equal to the

sum of the effects of the nervous phase and the chemical phase. Atropine, which paralyzes all secretory nerves, does not affect the second phase of secretion.

The Effect of Fats—Neutral fats have a peculiar effect on gastric secretion. On administration of fats, the amount and strength of the gastric juice are diminished. This effect is supposed to be due to a reflex originating in the duodenum. It is certainly not due to clogging of the orifices of the gastric glands, for substances with the same viscosity have no effect. Fats when administered to the mouth quickly enter the duodenum, and there augment the pancreatic secretion and diminish the gastric secretion. Fats become digested by the pancreatic juice, and the products of their digestion are regurgitated into the stomach, where they stimulate the gastric secretion by liberating the gastrin bodies from the pylorus. The effect of fats on the gastric secretion passes through three phases, the reflex, the inhibitory and the chemical.

It is obvious that in the case of complete feeding, the production of the gastric juice, depending on the two phases of secretion and on the inhibitory effect of fats, will be typical for each of the three main food substances. In the case of carbohydrate food, the secretion is very much like that in sham feeding—rapidly rising, then falling off within an hour or so, the nervous phase predominates, the chemical phase being negligible since the carbohydrates and their products have hardly any stimulating effect on gastric secretion. In the case of proteins, the chemical phase is well pronounced and superimposes itself on the nervous phase, and the secretion is prolonged at its maximum for over two hours. Then as the food leaves the stomach the secretion gradually diminishes. In the case of fats, the nervous phase is cut short as soon as food enters the duodenum, but the secretion is again favoured by the chemical phase setting in, the net result being a considerable prolongation of the period of gastric secretion. With mixed food, secretion will be the result of a summation of all these individual factors.

Gastric secretion is not evoked by the mechanical stimulation of the gastric mucous membrane, as was supposed before the true mechanism of gastric secretion was known. Water and alcohol both cause a slight secretion. The products of the digestion of carbohydrates do not seem to have any effect on gastric secretion, but carbohydrates themselves increase the strength of the gastric juice, and if they are present in the food in sufficient amount the concentration of pepsin may be actually doubled. The mechanism of this effect is not known.

The Pyloric Secretion—The secretion of the pylorus is strikingly different from that of the main part of the stomach. The pyloric secretion is never copious but is continuous, and is not increased by sham feeding. The pyloric juice does not contain HCl, and is very poor in pepsin. It is viscid on account of the presence of mucin. The secretion is not affected by section of all the nerves going to that part of the stomach, but it is greatly increased by local mechanical stimulation. It is immaterial whether the stimulation is caused by a food substance or something indigestible, provided that the texture is coarse, it will increase the production of the juice. Local stimulation with a glass rod may increase the secretion four or five-fold. Local application of chemical irritants, such as 0.5% HCl, a weak solution of carbolic suspension, of pepper, or an emulsion of mustard oil cut in water, increase secretion. But liquid and semi-liquid food substances, being devoid of mechanical stimulus, have no effect, either on local application or on introduction to the rest of the stomach. Even the extractive substances and the products of the digestion of fats which serve as stimuli for the fundal secretion, have no effect on the pyloric secretion. The function of the pyloric juice is to lubricate the narrow passage connecting the stomach with the intestine, and to provide a small additional amount of pepsin which helps in the digestive digestion as a whole.

The Movements of the Stomach—The gastric movements can best be studied by Cannon's method of direct observation by means of Röntgen rays. Bismut subnitrate or oxychloride is mixed with the food, and the animal or man is then X-rayed at different intervals. The obtained shadow of the stomach gives a good idea of the movements. This method can be checked by

other experiments, such as the determination of the rate at which the food or various liquids pass from the stomach into the duodenum, which can be done in an animal with a gastric fistula. An alternative method is to introduce a small rubber balloon through the gastric fistula, the balloon is connected to some kind of registration apparatus, and in this way pressure changes occurring in the stomach at each contraction can be observed. The relaxation of the cardiac orifice, which accompanies swallowing, extends also over the whole fundus of the stomach. This relaxation lowers the pressure within the stomach and makes room for the incoming food. As soon as the gastric contents become acid the cardiac orifice closes.

When food is taken, it accumulates in the fundus and is separated from the pylorus by a strong contraction (the transverse band or the prepyloric sphincter). After a few minutes, waves of contraction begin to appear slightly on the fundal side of the transverse band, and travel slowly towards the pylorus. These waves gradually increase in strength so that the pylorus may present a series of constrictions. The semi-digested food is thus brought into close contact with the pylorus mucous membrane. The pylorus, however, remains closed, and the food is therefore squeezed back, and forms a reflux stream towards the fundus. The food thus becomes thoroughly mixed with the gastric juice. The fundus of the stomach is now exercising a steady pressure by the contraction of its muscular walls, so that the digested food is forced to enter the pylorus. At varying intervals, the time depending on the nature of the food, the pylorus opens, and a little of the digested food enters the duodenum. As digestion proceeds, the fundus increases its pressure on the gastric contents while the pylorus opens at more frequent intervals. The stomach thus gradually empties itself, and the whole organ acquires the shape of a curved tube. At the end of digestion, the pylorus may even open to allow the passage of undigested material.

The contractions of the stomach, and its method of emptying, are very similar in man and the carnivorous animals. The foregoing description applies to the events which succeed the taking of a considerable mixed meal. If water alone is taken, the pylorus opens within a very short time, and the fluid reaches the duodenum within a few minutes. The importance of this becomes obvious when it is remembered that practically no absorption of water takes place in the stomach, but only in the intestine.

Pylorus and Duodenum—The movements of the two portions of the stomach can be observed also on anaesthetised animals, and even on a stomach which has been excised and placed in warm salt solution. They must therefore have their origin in the walls of the stomach itself. The vagus nerve supplies the muscles with fibres, the stimulation of which increases the contractions. The opening of the pylorus is more dependent on the nervous mechanism. If both vagi are cut, the emptying of the stomach becomes difficult on account of the diminution in the strength of the contractions, and also because the opening of the pylorus is not easily brought about. The food thus remains in a semi-digested form (since the secretion of the juice is also diminished) for a long time in the stomach, it undergoes putrefaction and the animal may die of autointoxication. The opening of the pylorus does not only depend on the intragastric events but also, as shown by Pavlov, on the condition of the duodenum. The pylorus remains firmly closed so long as the contents of the duodenum remain acid. If alkaline fluid or water is introduced into the stomach, and at the same time some weak acid is injected into the duodenum by means of a duodenal fistula, no fluid passes out of the stomach until the acid is neutralised by the secretion of the pancreatic juice.

When the pylorus is open, not only do the contents of the stomach enter the duodenum, but also the contents of the duodenum regurgitate into the pyloric cavity. Such regurgitation is a normal occurrence, and takes place in the digestion of any food, but is especially conspicuous in the digestion of fats. Fats are not digested in the stomach, they pass on to the duodenum where they are converted into glycerol and fatty acids which, in the alkaline medium, form soaps. While in the duodenum, fats cause (a) an inhibitory effect on gastric secretion and (b) a contraction

of the pylorus. As soon as the fats are digested, the pyloric sphincter opens, and large amounts of the products of the digestion together with bile and pancreatic juice regurgitate into the pylorus, where they increase gastric secretion by chemical stimulation. We must consider the action of the sphincter as dependent on the central nervous system and on the "acid control." Cannon's experiments have shown that "hunger pangs" are associated with and probably due to the rhythmic contractions of the stomach which occur about meal times, especially if they are delayed.

Vomiting—Vomiting may occur as a result of overdistension of the stomach, or the presence of irritating material, or from abnormal conditions of the brain. The first indication of vomiting is the feeling of nausea, accompanied by a profuse secretion of saliva. After a deep inspiration, the glottis is closed, and this is followed by a strong contraction of the diaphragm and of the abdominal muscles. At the same time the cardiac orifice is relaxed, and the gastric contents are passed out. The part played by the stomach itself is negligible. Vomiting is a reflex which can be excited by stimulation of the base of the pharynx, irritation of the stomach and from almost every abdominal organ. It is also evoked reflexly through the labyrinth or the eye, as in sea sickness, and is a conspicuous symptom of various diseases of the cerebrum and cerebellum. The nerve centre of vomiting is located in the medulla, and can be excited directly by various drugs such as tartar emetic, apomorphine, etc.

Pancreatic Secretion—The pancreas is the main digestive gland. It is the only gland which secretes a juice that contains enzymes capable of digesting all the three classes of foodstuffs. The carbohydrate-splitting enzyme (amylase or diastase) is secreted in a fully active form. The fat splitting enzyme (lipase) is partially active when secreted, and is rendered fully active by the action of the bile salts. But when the protein splitting enzyme (Trypsinogen) is secreted, it is completely inactive, it is converted into the active form (trypsin) by the co enzyme enterokinase of the intestinal juice.

The secretion of pancreatic juice has been studied in animals in which a fistula of the pancreatic duct has been established (the operation is similar to that of establishing a salivary fistula). Like the salivary glands and the glands of the stomach, the pancreatic gland is at rest except during the periods of digestion. The secretion begins soon after administration of food but it lags behind the gastric secretion, the maximum of which precedes the maximum of the pancreatic secretion by about an hour. The rate of pancreatic secretion, after a meal of proteins or carbohydrates, is on the whole very similar to that of the gastric secretion, but in the case of fats it is somewhat different. The similarity in the histological structure of the pancreas and the salivary glands has led physiologists to believe that the mechanism of secretion of these glands is the same, that is to say that the pancreatic secretion is controlled by a secretory nerve.

The Secretory Innervation of the Pancreas—The secretory fibres were discovered by Pavlov to run in the vagus nerve. However, stimulation of the vagus never produces anything like the normal quantity of the juice, and the whole secretion is rather peculiar. The vagus nerve has to be stimulated for a very long time before the secretion will appear. The vagus produces a strong contraction of the larger ducts of the gland, and thus prevents the juice from leaving the gland. But even independently of this contraction of the ducts, the amount of juice secreted is very small (about 10cc during a period of stimulation of 5-6 hours, as against a normal secretion of over 150cc after entry of $\frac{1}{2}$ pound of meat).

Furthermore, the composition of the juice so obtained is not like that which is secreted under normal conditions. It is over 10 times more concentrated, both in its protein and enzyme content. When boiled, it coagulates in a lump like egg white, while the normal juice becomes only slightly flocculent, it is also less alkaline than the normal juice, and therefore the trypsinogen of the "vagus juice" is apt to undergo spontaneous activation, and is more easily activated by enterokinase than the normal juice (the rate of activation is slower the more alkaline the juice). Nevertheless, the vagus nerve is a true secretory nerve, on stimu-

lation, it produces very considerable histological changes in the gland, far greater changes than in the case of normal secretion, and the nerves are completely paralysed by atropine. It may be concluded that, so far as causing the output of solids and enzymes is concerned, the vagus stimulation does the same or more than the taking of food, but as regards the passage of water from the blood into the ducts it is much less effective.

We also owe to Pavlov the discovery that introduction of acid into the duodenum of animals or anaesthetised animals is followed by a profuse pancreatic secretion, which lasts as long as the acid is being absorbed. The similarity between this effect and the secretion of saliva (on administration of acid into the mouth) led Pavlov to believe that the pancreatic secretion is also based on a reflex mechanism, the efferent path from which follows the vagi. He soon found, however, that section of the vagi, or in fact destruction of the entire nervous system, does not prevent the secretion of the pancreatic juice on administration of acid into the small intestine. Administration of acid into the stomach, into the large intestine or anywhere else has no effect whatever.

Gastric Juice—The discovery of the effect of acids is far more important than could be imagined at first sight. Pure gastric juice contains about 0.5% HCl but usually, on account of dilution with saliva and food, the acidity of the gastric contents is reduced to about 0.2-0.3%. The acid enters the duodenum and causes the pancreatic gland to begin to secrete. The first phase of gastric secretion becomes of outstanding importance, for it not only causes a further stimulation of gastric secretion, by giving rise to the products of digestion, but it also indirectly causes the continuation of digestion, for the acidity of the whole gastric contents leads to the secretion of the pancreatic juice.

Appetite, in that it augments the nervous phase of gastric digestion, is the trigger that sets the whole digestive tract into activity. This fact so much impressed Pavlov that he organized, next to his laboratory, a special department where the gastric juice of dogs was (and still is) obtained by sham feeding in large quantities. This material was sterilized and sold at a low price to the general public at the rate of several thousands of bottles a year. The improvement of digestion and nutrition in cases of dyspepsia, cancer, achlorhydria, loss of appetite and chronic gastritis was immense.

The Chemical Phase of Pancreatic Secretion—The mechanism of the secretory effect of acid was discovered by Bayliss and Starling in 1902. They found that, on pounding up some scrapings of the intestinal mucous membrane with dilute ac.2 and filtering, they obtained a filtrate that produced a copious flow of pancreatic juice when it was injected into the blood. This discovery was not only of great value in elucidating the mechanism of pancreatic secretion, but it was also of general importance in physiology, for it was the first time it could be shown that a chemical substance, manufactured under definite conditions by one organ, could be liberated into the blood stream and conveyed to another organ, which it would excite to activity. Since this discovery, a number of other substances of the same nature have become known. Bayliss and Starling described them as chemical messengers, and gave them the name of *hormones* (*q.v.*). The hormone of the small intestine was called secretin, or pancreatic secretin, to distinguish it from other members of the same class.

Secretin can be extracted from the small intestine by various solvents, e.g., water, alcohol, salt solutions, etc. It is not an enzyme, and is not destroyed by boiling. That secretin is normally transported by the blood stream is most convincingly shown by experiments with crossed circulation, and perfusion of the isolated pancreatic gland. If two arteries of two dogs are connected in such a manner that the blood of one animal freely mixes with that of the other, and if acid is injected into the duodenum of one of the animals, the pancreatic glands of both dogs begin to secrete. Also, if a pancreas is cut out of the body and perfused with blood under pressure so as to keep it alive, and if a solution of secretin is injected into the blood, the isolated pancreas immediately responds by secretion of the juice. In this secretory mechanism, we have a very striking example of a correlation between the activities of two different parts of the body, effected

by chemical means. When the acid chyme enters the intestine, a certain amount of secretin is liberated into the blood stream. The resulting secretion of the alkaline pancreatic juice neutralizes the acid chyme, and the liberation of secretin (and therefore of pancreatic juice) comes to an end. So long as the duodenal contents are acid, the pylorus remains closed, but as soon as they are neutralised, the pylorus opens to allow another portion of the acid gastric contents to pass. In this way, the pancreatic secretion is maintained throughout the whole period of digestion.

Secretin—The chemical composition of secretin is not known, and secretin has not yet been obtained in a pure form. The usual extracts of the mucous membrane of the small intestine contain, besides secretin, a large number of impurities, especially a substance named histamine, which has a considerable vasodilator effect on the capillaries of all organs. Thus after the injection of crude preparations of secretin, the blood pressure falls, sometimes very considerably. It has been proved that the induced pancreatic secretion is not caused by the fall of blood pressure itself. The proof rests on the following observations. The vasodilatory substances can be extracted from almost every organ, but secretin is only present in the small intestine. With certain solvents, it is possible to extract a depressor free secretin. In slightly alkaline medium, secretin is destroyed while the vasodilatory substances remain intact. The action of secretin is not paralysed by atropine, showing that secretin acts directly on the pancreatic cells, and not on the nerve endings of the secretory nerves. The composition of the secretion and the chemical mechanism of pancreatic secretion are apparently the same in all animals, at least, secretin extracted from the intestine of any animal will cause pancreatic secretion in any other animal. In the foetus, secretin is found in a very early stage of development.

The question now arises as to the correlation between the nervous and the chemical mechanisms of pancreatic secretion. The correlation is not yet clear, but we know of one instance in which the secretion, or rather the composition of the juice, is determined by the cooperation of the vagus nerve—that is in the case of injection of fats. Injection of neutral fats or of soaps into the duodenum evokes a secretion of very concentrated juice that is rich in enzymes. After section of the vagi, or after injection of atropine, the quantity of the secreted juice is unaltered, but it is now poor in enzymes. In many cases also sham feeding, when the entry of the gastric juice into the duodenum is prevented, will evoke a small secretion of very concentrated juice, some time before the appearance of gastric secretion, this secretion is absent after section of the vagi.

Stimulation of the vagi, superimposed upon the pancreatic secretion which has been evoked by injection of secretin, does not modify the rate of secretion but greatly enriches the juice in enzymes. It seems that the nervous mechanism is chiefly concerned with the removal from the cells of the pre-stored enzymes, while the chemical mechanism regulates the passage of water and alkali from the blood through the gland into its system of ducts. Histological observations support this point of view since, after the considerable secretion of pancreatic juice evoked by chemical means, the pancreas looks only lightly exhausted while after the small secretion evoked by stimulation of the vagus the gland becomes a picture of maximal exhaustion.

The Secretion of Bile—The liver is the largest gland in the body, but its digestive function is one of secondary importance, as compared with the rôle it plays in the chemical alteration of substances after they have been absorbed into the blood and its function as an excretory organ of various substances amongst which the products of the decomposition of haemoglobin are the chief. The production of bile by the liver cells is continuous, but the entry of the bile into the digestive tract is intermittent, and is only to some extent related to the periods of digestion. The secreted bile accumulates in the gall bladder and in the large bile duct, the entry into the intestine being prevented by a small sphincter at the end of the common bile duct. While the bile remains in the gall bladder, it undergoes concentration on account of absorption of water and secretion of mucin by the walls of the bladder.

From the point of view of digestion, the only important constituents of bile are the bile salts (sodium taurocholate and glycocholate). The digestive functions of bile are—

- (1) Activating the lipase of the pancreatic juice
- (2) Increasing the emulsification of fats by lowering the surface tension
- (3) Dissolving fatty acids and soaps
- (4) Increasing the peristaltic movements of the intestinal tract
- (5) Increasing the bile production on reabsorption of bile salts into the blood

During the periods of digestion, the flow of bile is increased. This is due to two factors—(a) the emptying of the gall bladder, and (b) an increased formation of bile.

The muscular wall of the gall bladder is under a nervous control, the vagus conveying motor, and the sympathetic inhibitory fibres. The entry of the products of gastric digestion and of the acid chyme into the duodenum sets the reflex in operation. The actual secretion of bile, however, is independent of the nervous system, and continues even after all the nerve connections of the liver have been severed. It is mainly dependent on the blood supply to the liver and, if other conditions are the same, the bile flow increases with increase of blood flow. Absorption of food substances, of acid, and especially of fats increases the production of bile. This is ascribed by some to the liberation of the pancreatic secretion.

The bile salts are reabsorbed in the intestine and conveyed via the portal vein back to the liver, which removes them from the blood, thus preventing their entry into the general circulation where they would be intensely poisonous (see JAUNDICE or ICTERUS). The bile salts increase the production of bile, and thus a comparatively small amount of bile salts undergoes repeated resecretion during a comparatively short time. The entry of bile into the digestive tract, and therefore the stimulating effect of bile salts upon bile production, is stopped at the end of digestion by the closure of the sphincter of the common bile duct.

The Intestinal Juice (Succus Entericus)—The secretion of the intestinal juice, like that of the pyloric juice, is continuous. The secretion is studied in animals in which one or another part of the intestinal tract is transplanted so as to open to the outside of the abdominal cavity. Since the intestine hangs on the loose mesentery, the blood vessels and nerves of the transplanted part remain intact. The continuity of the rest of the tract is re-established. Animals operated on in this manner live as long as normal animals, and do not suffer in their digestion or general condition.

The intestinal juice on standing divides itself into 2 fractions, a sediment which is chiefly composed of the mucus secreted by the goblet cells of the digestive tract and desquamated epithelium, and a liquid part containing enzymes (the enzymes are enterokinase, erepsin, nuclease, amylase, invertase, lactase and lipase maltase, the Brunner's glands of the duodenum secrete an enzyme similar to pepsin). The lower down the tract, the larger is the sedimentation, until the secretion in the large intestine is composed of mucus and is devoid of enzymes (See VITRITION).

There are no definite indications of any nervous control of intestinal secretion. Section of the nerves produces a great increase in the flow, but this is usually attributed to the hyperaemia ensuing after section of the nerves which contain a large amount of vasoconstrictor fibres. Some physiologists regard this secretion as due to section or special inhibitory nerves.

Intestinal injections of secretin increase the secretion of intestinal juice and it has regarded the mechanism of intestinal secretion as identical with that of pancreatic secretion, namely that in both cases, the stimulus is due to the liberation of the same agent, secretin. However, experiments on animals with a transplanted loop of the intestinal tract (kept under normal conditions) make this view unreliable. On feeding such an animal the secretion of the transplanted part is not increased as it would have been if the hormone mechanism were the operative factor. Pavlov's experiments show that the stimulus for intestinal secretion is, like that of pyloric secretion, local mechanical stimulation of the mucous membrane.

Some Experiments—The following experiments may serve to illustrate this point. The secretion of the intestinal juice from the small isolated portion was measured before and after feeding the animal with various food substances. The juice was collected by means of a small tube inserted in the isolated loop. Before feeding, the spontaneous secretion varied between 2.0 and 2.8 cc, after intake of meat, it was 2.5 cc, after bread 3.0 cc, after milk 1.7 cc, and after mixed food 1.6 cc. Only in the case of feeding with fats

did the secretion of the isolated portion slightly but definitely increase (from 3.0 to 5.0 cc). With these results should be compared the experiments with local mechanical and chemical stimulation of the transplanted part. The spontaneous secretion was 0.0–0.5 cc per hour, when a rubber tube was introduced into the intestinal loop, the secretion increased to 4 cc, when glass beads were placed in the intestines, it increased to 8.7 cc, when 0.5% HCl was injected into the intestine and then removed, the hourly secretion increased to 20 cc. The stimulation by either of the above methods of some part of the intestine has no effect on the rest of the tract, showing that the effect is mainly if not entirely local. These local stimuli have hardly any effect on the secretion of the sediment, they only increase the production of the enzyme-containing liquid part of the juice.

Some observers have found that stimulation of the vagus nerve increases the secretion of the juice after a very long latent period. It is possible, however, that the increased flow is due to a more vigorous contraction of the intestines, for the vagus is the motor nerve of the intestinal muscles.

A very interesting correlation has been discovered as regards the concentration of enterokinase in the intestinal juice and the pancreatic juice. The transplanted loop of the intestine secretes a juice which becomes progressively poorer in enterokinase, so that a few months after the operation it almost entirely loses the power to activate trypsinogen (*see ENZYMES*). If however the mucous membrane is brought for a short time (2–3 minutes) into contact with the pancreatic juice (the juice may be diluted to as much as one in 1000), the concentration of enterokinase increases. Alkali and boiled pancreatic juice have no such effect. The concentration of other enzymes of the intestinal juice is not affected by such treatment of the intestine with pancreatic juice.

The Movements of the Small Intestine.—It is known that the intestinal tract is in a state of constant movement, the analysis of which presents great difficulties because several types of contraction may occur simultaneously or in rapid succession, either at the same point or at neighbouring positions. Different authors have given different descriptions of these movements, and have used different nomenclatures but in spite of this confusion it may be said that the small intestine exhibits three kinds of contractions. These are as follows:—(a) the rhythmic segmentation (also known as pendular movements or swaying movements), (b) the peristaltic contraction (also known as the myenteric reflex), and (c) the tonic contractions.

Rhythmic Contractions.—Direct observations of an exposed part of the intestine show that slight waves of contraction pass over its surface. Records by means of instruments show that both the circular and the longitudinal muscular coats take part in these contractions, which recur at the rate of 10–15 a minute. These contractions involve only short stretches of the intestine. They easily can be produced artificially by stimulating the gut either electrically or mechanically. On application of such a stimulus, the part immediately stimulated quickly contracts, the contraction spreading one or two centimetres along the intestine. These rhythmic contractions may originate spontaneously in any part of the intestinal tract, especially at those parts which are subjected

to some tension. The propagation of this contraction goes from muscle fibre to muscle fibre at an average rate of about 5 cm per second.

These rhythmic contractions are unaffected by section of all the nerves of the intestine, in fact they are entirely myogenic in origin. They are even independent of the local nervous network of the intestinal wall, for strips removed from the longitudinal coat of the small intestine entirely free from any remains of the nerve plexus continue their rhythmic contraction. (The nervous network of the intestine is made up of Auerbach's plexus and Meissner's plexus.)

In order to observe the rhythmical contractions, isolated portions of the intestine can be removed from an animal after its death, these portions should be kept at body temperature, surrounded with a solution containing salts in the same proportion as those in blood (Ringer's fluid), and richly supplied with oxygen. In the normal animal, the rhythmic contractions cause a thorough mixing of the contents of the gut with the secretions of the various glands, but they do not help to pass the food along the intestinal tract, for each contraction squeezes the food in both directions. A column of food may thus remain at the same level in the gut for a considerable time.

Peristaltic Contractions.—The onward progress of the food is caused by true peristaltic contractions which involve contraction of the intestine above the food mass, and relaxation below. This contraction and relaxation travels down the intestinal tract in the form of two waves, and in this way the food is slowly propelled towards the large intestine. The peristaltic contractions involve the co-operation of the local nervous system of the intestine, and they are absolutely abolished by painting the intestine with drugs which paralyse nerves (e.g., nicotine, cocaine), but still continue after severing the nervous connection between the intestine and the brain and spinal cord. The direct irritating effect of food, or the application of an experimental stimulus, evokes an immediate contraction above and relaxation below (sometimes described as "the law of the intestines"). Anti peristalsis is not observed in the small intestine.

Tonic Contractions.—The third type of movement, which is known as the tonic contraction, is common to all plan muscles, and is determined by a state of sustained partial contraction of the muscle. Neither during the wave of relaxation observed as the forerunner of the wave of contraction in peristalsis, nor during the periods in between the rhythmic segmentation, is the intestine completely relaxed, it always maintains a certain tone, which may be greater or less. Thus the two forms of contraction (already described) are superimposed upon the tonically contracted state of muscles. In some cases, the intestinal tone may be intense. It is claimed that colic pains are due to this form of contraction.

Although the mechanism of all these three forms of contraction is entirely peripheral, they can be increased or decreased by impulses from the central nervous system. The vagus nerve carries nerve fibres to the intestine which stimulate its movements, while the splanchnic nerves diminish or even abolish them. The lowest 3 cm of the small intestine exhibits a thickening of the circular muscular coat, the ileocolic sphincter (valve), which relaxes in front of a peristaltic wave and contracts if there is any regurgitation from the large intestine. This sphincter presents a marked contrast to the rest of the small intestine in that its innervation is reversed, the vagus being the inhibitory and the splanchnic the excitatory nerve.

The Movements of the Large Intestine.—The contents of the small intestine are gradually transferred into the large intestine. In carnivora, the digestion and absorption are both nearly completed at the ileocolic valve, but in herbivora a large part of the processes of digestion and absorption occur in the large intestine and in the caecum. As regards his large intestine, man takes an intermediate position between these two groups of animals.

The movements of the large intestine can best be observed by means of the X-ray method, after feeding a meal containing some bismuth. The food first fills the proximal part of the large intestine. The distension brings about a wave of contraction which starts at the end portion of the ascending colon, and slowly travels

FIG. 3.—DIAGRAM OF NORMAL POSITION OF COLON OR LARGE INTESTINE IN MAN SHOWING THE TIME IN HOURS OF ARRIVAL OF FOOD AT VARIOUS LEVELS.

in a backward direction, passing the food toward the caecum, the ileocolic valve prevents its escape into the small intestine. These contractions are not preceded by a wave of relaxation and therefore should not be regarded as antiperistaltic waves. As the whole contents cannot escape into the caecum, certain portions slip back. These movements thus have the same effect as those of the pylorus, they bring the food into closer contact with the walls of the alimentary canal. In this way the intestinal movements favour the absorption of substances that escaped absorption in the small intestine.

The distension of the caecum occasionally excites a true peristaltic wave which travels in a forward direction and drives the semi-solid residue of the food toward the distal part of the colon. The intensity of the peristaltic waves and of the backward contraction vary greatly in different kinds of animals, and even in different individuals of the same species. In man they are not well pronounced, and the caecum and the ascending colon seem to be more or less passive.

About 400 g of semisolid material pass the ileocolic valve daily, of this amount, about 250 g is water with some nutrient material, which is absorbed in the large intestine, the remaining 150 g form the faeces.

The large intestine, like the small, has a nervous system of its own in the form of a network of nerve cells and fibres lying in between the muscular layers. The movements of the large intestine are primarily dependent on this network, but they can be increased under the influence of the pelvic visceral nerve, or diminished by the inferior mesenteric nerves which belong to the sympathetic nervous system.

A distinguishing feature of the distal colon is its complete subordination to the spinal centres. It remains inactive until, on account of distension, it is reflexly excited through the pelvic visceral nerve, it is then completely emptied.

In man, the emptying of the rectum is largely assisted by contractions of voluntary muscles of the pelvis and of the abdominal wall.

In herbivora, the large intestine plays an important part in the digestion of cellulose, not because of the secretion of some special enzyme which could effect this digestion, but because of the rich bacterial flora of the large intestine.

The splitting of cellulose is caused by the action of bacteria, and it results in the formation of simpler carbohydrates, viz. sugars. Thus the cellulose which forms vegetable cell walls can be utilized by the animal.

DIGESTIVE ORGANS. The digestive system is made up of the gastrointestinal tract, consisting of the mouth, throat, oesophagus, stomach and intestines, and of glands such as the salivary glands, the pancreas and the liver which pour the secretions into the tract in order to accomplish the digestion of the food. (See ALIMENTARY CANAL, ALIMENTARY SYSTEM, DISEASES OF THE, DIGESTION, INTESTINAL, PANCREAS, STOMACH, THROAT.)

DIGG'S LIONARD

SIR DUDLEY DIGGES (1583-1639), the son of Thomas, was a judge and diplomat. Graduated with the degree of B.A. from University College, Oxford, in 1601, he became an early shareholder in the East India Company and served as a member of parliament at various times. In 1618 he represented the king, James I., in Russia and in 1620 went to Holland where he unsuccessfully attempted to settle by negotiation the disagreements between the East India companies of the two countries. In 1636 he became master of the rolls. Sir Dudley and his father jointly wrote *Four Paradoxes or Politike Discourses* (1604).

DUDLEY DIGGES (1613-1643), son of Sir Dudley Digges was a staunch supporter of Charles I., whom he defended in a number of political works such as *A Review of the Observations upon some of His Majesty's late Answers and Expresses* (1643) and *The Unlawfulness of Subjects taking up arms against their Sovereign, in what case soever* (1643).

DIGGES, WEST (1720-1786), English actor, made his first stage appearance in Dublin in 1749 as Jaffer in *Venue Preserved*, and both there and in Edinburgh until 1764 he acted in many tragic roles with success. He was the original "young Norval" in Home's *Douglas* (1756). His first London appearance was as Cato in the Haymarket in 1777, and he afterward played Lear, Macbeth, Shylock and Wolsey. In 1781 he returned to Dublin and retired in 1784. He died in Cork on Nov. 10, 1786.

DIGIT, literally a finger or toe (Lat. *digitus*, finger), and so from counting on the fingers a single numeral or, from measuring, a finger's breadth. In astronomy a digit is the 12th part of the diameter of the sun or moon, it is used to express the magnitude of an eclipse.

DIGITALIS. In pharmacy, the dried leaf of the common foxglove (*g v*), *Digitalis purpurea* Linné. It was first introduced into medicine as a diuretic (stimulant of urine secretion) in dropsy in 1775 by William Withering of Birmingham, Eng., who recognized it as the active ingredient of an old woman's secret formula.

Three cardiac glucosides have been isolated in crystalline form from *Digitalis purpurea*, digitoxin, gitoxin and gitalin. All three have essentially similar pharmacological actions although they differ in the rate in which they are absorbed and eliminated in the body and also in their solubilities in various solvents. In addition, digitalis also contains a number of saponins which probably modify the effect of the cardiac glucosides without producing cardiac effects themselves.

The beneficial actions of the cardiac glucosides in heart disease include a tonic effect on the heart, with diminution of the volume of the organ and increased cardiac output, a slowing of the pulse, and a slowing of the conduction of impulses throughout the heart. These effects are produced at near toxic doses and are frequently accompanied by gastrointestinal upsets, caused probably by a stimulation of the vomiting centre by reflexes set up by the cardiac effects. The diuretic effect of digitalis is secondary to its improvement of the circulation and is not due to any specific action on the kidney.

Digitalis is indicated in congestive heart failure from any cause, being most effective in cases of auricular fibrillation. It leads to cumulation of the drug in the body because of excretion and destruction. Because of this cumulation the use of the small margin between therapeutic and toxic toward effects are not uncommon and may consist of gastrointestinal upsets and visual disturbances or more alarming irregularities. It is usually administered by mouth in the form of tablets or of the dried leaf. The purified principles may be given usually, though this is seldom necessary or desirable.

(F O K)

DIGNE, the chief town of the department of the Basses Alpes, in southeast France, 14 mi. by a branch line from the way line between Grenoble and Avignon. Population (1936), 5,689, in 1946, 6,845. The Duma of the Rô was the capital of the Bodionti. From the early 6th at least it has been an episcopal see, which till 1790 was in the ecclesiastical province of Embrun, but since 1802 in that of Provence. It suffered much during the religious wars of the

16th and 17th centuries. The Ville Haute is built on a mountain spur on the left bank of the Bléone river, and above its narrow, winding streets towers the present cathedral church (late 15th cent.), largely reconstructed in modern times, and the former bishop's palace (now the prison). The fine Boulevard Gassendi separates the Ville Haute from the Ville Basse, which is of modern date. The old cathedral (Notre Dame du Bourg) (13th cent.) is now disused except for funerals. The neighbourhood of Dijon is rich in orchards, which have long made the town famous in France for its preserved fruits and confections, honey and yellow wax.

DIJON, a town of east central France, in the department of Saône-et-Loire, on the right bank of the Loire, 55 mi WNW of Mâcon on the Paris Lyon railway. Pop. (1936) 5,668. It is situated at the meeting places of the Loire, the Lateral canal of the Loire and the Canal du Centre, which here crosses the Loire by a fine aqueduct. The town carries on considerable manufactures of faience, pottery and porcelain. The port on the Canal du Centre trades in timber, sand, iron, coal and stone.

DIJON, a town of eastern France, capital of the department of Côte d'Or and formerly capital of Burgundy, 195 mi SE of Paris on the Paris Lyon railway. Pop. (1936) 93,929.

Under the Romans Dijon (*Duconense castrum*) was a *vicus* in the *civitas* of Langres. In the 2nd century it was the scene of the martyrdom of St. Benignus (Benigne, *unig* Berlin, Berain), the apostle of Burgundy. About 274 the emperor Aurelian surrounded it with ramparts. Gregory of Tours, in the 6th century, comments on the strength and pleasant situation of the place, expressing surprise that it does not rank as a *civitas*. The dukes of Burgundy acquired Dijon early in the 11th century. The communal privileges, conferred on the town in 1182 by Hugh III, duke of Burgundy, were confirmed by Philip Augustus in 1183, and in the 13th century the dukes took up their residence there. For the decoration of the palace and other monuments built by them, eminent artists were gathered from northern France and Flanders, and during this period the town became one of the great intellectual centres of France. The union of the duchy with the crown in 1477 deprived Dijon of the splendour of the ducal court, but to counterbalance this loss it was made the capital of the province and seat of a *parlement*. Its fidelity to the monarchy was tested in 1513, when the citizens were besieged by 50,000 Swiss and Germans, and forced to agree to a treaty so disadvantageous that Louis XII refused to ratify it. In the wars of religion Dijon sided with the League, and opened its gates to Henry IV only in 1595. The 18th century was a brilliant period for the city, it became the seat of a bishopric, its streets were improved, its commerce developed, and an academy of science and letters founded, while its literary salons were hardly less celebrated than those of Paris. The neighbourhood was the scene of considerable fighting during the Franco-Prussian War, which was, however, indirectly of some advantage to the city owing to the impetus given to its industries by the immigrants from Alsace.

Dijon stands on the western border of the fertile plain of Burgundy, at the foot of Mont Afrique, the north-eastern summit of the Côte d'Or range, and at the confluence of the Ouche and the Suzon, it also has a port on the canal of Burgundy. The great strategic importance of Dijon as a centre of railways and roads, and its position with reference to an invasion of France from the Rhine, led to the creation of a fortress forming part of the Langres group. There is no *enceinte*, but on the east side detached forts, 3 to 4 m distant from the centre, command all the great roads, while the hilly ground to the west is protected by Fort Hauteville to the NW and the "groups" of Motte Giron and Mont Afrique to the SW. Including a fort near Saussy (about 8 m to the NW) protecting the water-supply of Dijon, there are eight forts, besides the groups above mentioned. The old churches and historic buildings of Dijon are to be found in the irregular streets of the old town, but industrial and commercial activity has been transferred to the new quarters beyond its limits.

The cathedral of St. Bénigne, originally an abbey church, was built in the latter half of the 13th century on the site of a

Romanesque basilica, of which the crypt remains. The west front is flanked by two towers and the crossing is surmounted by a slender timber spire. The plan consists of three naves, short transepts and a small choir, without ambulatory, terminating in three apses. In the interior there is a fine organ and a quantity of statuary, and the vaults contain the remains of Philip the Bold, duke of Burgundy, and Anne of Burgundy, daughter of John the Fearless. The site of the abbey buildings is occupied by the bishop's palace and an ecclesiastical seminary. The church of Notre Dame, typical Burgundian Gothic (1252-1334) is distinguished for the grace of its interior and the beauty of the western façade. The portal consists of three arched openings, above which are two stages of arcades, open to the light and supported on slender columns. A row of gargoyles surmounts each storey of the façade, which is also ornamented by sculptured friezes. A turret to the right of the portal carries a clock called the Jaquemart, on which the hours are struck by two figures. The church of St. Michel belongs to the 15th century. The west façade, the most remarkable feature of the church, is, however, Renaissance. The vaulting of the three portals is of exceptional depth owing to the projection of the lower storey of the façade. Above this storey rise two towers of five stages, the fifth stage being formed by an octagonal cupola. The columns decorating the façade represent all the four orders. The design of this façade is wrongly attributed to Hugues Symbin (*fl.* c. 1540), a native of Dijon, and pupil of Leonardo da Vinci, but the sculpture of the portals, including "The Last Judgment" on the tympanum of the main portal, is probably his work. St. Jean (15th century) and St. Étienne (15th, 16th and 17th centuries), now used as the exchange, are the other chief churches. Of the ancient palace of the dukes of Burgundy there remain two towers, the Tour de la Terrasse and the Tour de Bar, the guard room and the kitchens, these now form part of the *hôtel de ville*, the rest of which belongs to the 17th and 18th centuries. This building contains an archaeological museum, the archives of the town, and the principal museum, which, besides paintings and other works of art, contains the magnificent tombs of Philip the Bold and John the Fearless, dukes of Burgundy. These were transferred from the Chartreuse of Dijon (or of Champmol), built by Philip the Bold as a mausoleum, now replaced by a lunatic asylum. Relics of it survive in the old Gothic entrance, the portal of the church, a tower and the well of Moses, which is adorned with statues of Moses and the prophets by Claus Sluter (*fl.* end of 14th century), the Dutch sculptor who also designed the tomb of Philip the Bold. The Palais de Justice, which belongs to the reign of Louis XII, is of interest as the former seat of the *parlement* of Burgundy. Dijon possesses several houses of the 15th, 16th and 17th centuries, notably the Maison Richier in the Gothic, and the Hotel Vogué in the Renaissance style.

The town is important as the seat of a prefecture, a bishopric, a court of appeal and a court of assizes, and as centre of an academic (educational district). There are tribunals of first instance and of commerce, a board of trade-arbitrators, a chamber of commerce, an exchange and an important branch of the Bank of France. Its educational establishments include faculties of law, of science and of letters, a preparatory school of medicine and pharmacy, a higher school of commerce, a school of fine art and a conservatoire of music.

Dijon is well known for its mustard, and for the black-currant liqueur called *cassis de Dijon*, its industries include the manufacture of machinery, automobiles, bicycles, soap, biscuits, brandy, leather, boots and shoes and hosiery. There are also flour mills, important printing works, vineyard works and, in the vicinity, nursery gardens. The state has a large tobacco manufactory in the town. Dijon has considerable trade in cereals and wool, and is the second market for the wines of Burgundy.

DIKE or DYKE, a trench dug out of the earth for defensive and other purposes (*cf.* Dutch *dijk*, Ger *Teech*). Water naturally collects in such trenches, and hence the word is applied to natural and artificial channels filled with water, as appears in the names of many narrow waterways in East Anglia "Dike"

is also used of the bank of earth thrown up out of the ditch, and so of any embankment, dam or causeway, particularly the defensive works in Holland, the Fen district of England, and other low-lying districts which are liable to flooding by the sea or rivers (See *HOLLAND and FENS*). In Scotland any wall, fence or even hedge, used as a boundary, is called a dyke. In geology the term is applied to wall like masses of rock (sometimes projecting beyond the surrounding surface) which fill up vertical or highly inclined fissures in the strata.

DIKKA, in architecture, a raised tribune or platform in a Mohammedan mosque, from which the service is directed and the Koran read.

DILAPIDATION, a term meaning in general a falling into decay, but more particularly used in the plural in English law for (1) the waste committed by the incumbent of an ecclesiastical living, (2) the disrepair for which a tenant is usually liable when he has agreed to give up his premises in good repair (see *EASEMENT, FLAT, LANDLORD and TENANT*, as to limited owners, see *WASTE*).

In the eye of the law an incumbent of a living is a tenant for life of his benefice, and any waste, voluntary or permissive, on his part must be made good. Under the old law, proceedings might be taken against the dilapidating incumbent in the ecclesiastical court, or an action in the courts of common law could be brought by the successor upon the custom of England against the previous incumbent or his personal representatives if he were dead. And if such a thing should happen, this law might still have to be applied in the case of bishops or cathedral dignitaries or officers. But for parochial incumbents provision was made in 1873 by the Ecclesiastical Dilapidations Act of that year, which Act however has now been superseded by the Ecclesiastical Dilapidations Measure 1923 which covers the whole ground.

By this measure, diocesan dilapidation boards are appointed who are to cause first inspections to be made of the buildings of every benefice. These first inspections are to be made within seven years of the passing of the Measure or earlier if the benefice becomes vacant or is put under sequestration. The surveyor is to report whether any and if so what repairs are needed, and to divide them into ordinary repairs and structural repairs, and to subdivide the latter into those which do not or do admit of delay, and if there has been any mischief due to deliberate action or gross neglect, he is to state the cost of these separately and call them "wilful dilapidations." For these latter the incumbent is to be liable at once. Opportunity is given to any party interested to object to the report of the surveyor on any point, and the board is finally to determine.

If the inspection is on a vacancy, and the late incumbent is not protected by a certificate under the old Act, he or his personal representatives must pay to Queen Anne's Bounty the cost of ordinary and immediate structural repairs, as determined by the Board. If the first inspection is not on a vacancy and the incumbent or the sequestrator is not protected by a certificate under the old Act he is similarly liable, but in case of personal poverty or the benefice being less than £150 a year, there are provisions for his relief.

As to the future, Queen Anne's Bounty is to make an assessment first for a "repair rate" to cover the execution of repairs required by an order of the dilapidation board, except those already provided for and those for which the cost is spread over more than five years, secondly for an "insurance rate" to provide for reinstating the buildings in case of fire, and thirdly for an "administration rate" to cover office expenses and surveyor's fees. For repairs, the cost of which is to be spread over a longer period than five years, there is to be a "long assessment" in lieu of an ordinary assessment.

There are numerous provisions directing the application of the moneys raised and the execution of repairs and giving power to Queen Anne's Bounty to advance loans and to make grants in the case of poor livings, and concerning timber growing on the glebe. The broad effect of the Measure is to substitute annual payments in the nature of premiums of insurance in lieu of a capital liability.

In the United States, the term means the neglect of necessary repairs of a building, the suffering of it to fall into a state of decay or the unauthorized pulling down of the building or any part of it. (See *LANDLORD and TENANT*.)

DILATATION, a term used in medicine to denote the widening or enlarging of a cavity, orifice or hollow viscus beyond its normal dimensions. It may arise pathologically from obstructions in hollow viscera such as the gastrointestinal tract and the urinary and biliary tracts. Fluid accumulates above the obstruction, leading to a dilatation of the viscus. This usually leads to an increased muscular activity above the obstruction which produces a sensation of pain and may ultimately lead to a thickening of the muscular wall. Following the removal of the obstruction the viscus may or may not assume its original dimensions depending on the elasticity of its muscular layers. In dilatation of the ventricles of the brain, expansion of the brain is limited by the rigidity of the skull, hence hydrocephalus (*q.v.*) results. Digital dilatation, dilatation of a cavity or orifice by means of a finger is a method commonly employed in physical diagnosis.

The term is used in connection with heart disease when the muscle is weakened and one or more cavities dilated, thus causing interference with normal circulation.

The term is also used to describe certain operative procedures when an orifice or passage is dilated with various types of instruments. (F. L. A.)

DILATORY, delaying, or slow, in law a "dilatory plea" is one made merely to delay the suit.

DILEMMA is the name of a special type of reasoning. In its commonest form its conclusion presents one with two alternatives. When employed in debate the usual aim is to present alternatives both of which are unpalatable to the opponent. Thus, *e.g.* in answer to the contention of a protectionist that protective import duties *both* increase revenue and stimulate home industry, it has been argued "If protective duties increase revenue, they cannot also stimulate home industry, and if they stimulate home industry, they cannot also increase revenue."

"But they do either the one or the other."
"Therefore they either cannot stimulate home industry, or they cannot increase revenue." (That is they cannot do both at once.) The unpalatable alternatives are called the "horns" of the dilemma. This familiar use of the dilemma has led to an extension of its meaning, and the term is applied popularly to any kind of situation in which one is confronted with unsatisfactory alternatives, as, *e.g.*, when a country, exhausted by war, finds itself in the dilemma of either impoverishing its people or repudiating its debts.

Valid arguments in the form of the dilemma are not very common, hence few situations can be adequately summed up in two alternatives. The dilemma is consequently used frequently in a rather loose manner by plausible orators. Hence there is an impression abroad that dilemmas are merely sophistical tricks. But this is a mistake. Dilemmas can be, and sometimes are, quite sound. Their association with political discussions or merely captious argumentations is accidental, and the alternatives which their conclusions present need not be unpalatable. (See *Logic*.)

DILETTANTE, an Italian word for one who delights in the fine arts, especially in music and painting. Properly the word refers to an "amateur" as opposed to a "professional" cultivation of the arts, but is often used in a depreciatory sense of one who is only a dabbler. The Dilettanti Society, founded in 1733-34, still exists in England. A history of the society, by Lionel Cust, was published in 1898.

DILIGENCE, in common law, a term which is substantially equivalent to "care." In Scots law it is a general term for the process by which persons, lands or effects are attached on execution, or in security for debt. (See *NEGLECT*.)

DILKE, CHARLES WENTWORTH (1780-1864), an English critic and antiquarian, was born on Dec. 8, 1780. After studying at Cambridge, he entered the navy pay office. From 1814 to 1816 he edited *Old English Plays* (6 vols.), from 1830 to 1846 the *Athenaeum*, and from 1846 to 1849 was manager of the *Daily News*. He then became a regular contributor to the

Athenaeum, his valuable essays for it on Elizabethan drama, on the literary history of the 17th and 18th centuries, and especially on Pope, being collected as *Papers of a Critic* (2 vols, 1875) Dilke died in Hampshire on Aug. 10, 1864.

DILKE, SIR CHARLES WENTWORTH, BART (1810-1869), English politician, son of Charles Wentworth Dilke, proprietor and editor of *The Athenaeum*, was born in London on Feb. 18, 1810, and was educated at Westminster school and Trinity Hall, Cambridge. He studied law, and in 1834 took his degree of LL.B., but did not practise. He assisted his father in his literary work, and was for some years chairman of the council of the Society of Arts. He took a prominent part in the affairs of the Royal Horticultural Society and other bodies, including the executive committee of the Great exhibition. In 1853 Dilke was one of the English commissioners at the New York Industrial Exhibition, and in 1862 one of the five royal commissioners for the second Great Exhibition. Soon after the death of the prince consort he was created a baronet. In 1865 he entered parliament as member for Wallingford. In 1869 he was sent to Russia as representative of England at the horticultural exhibition held at St. Petersburg (Leningrad). His health, however had been for some time failing, and he died suddenly in that city on May 10, 1869.

DILKE, SIR CHARLES WENTWORTH, BART (1843-1911), son of the preceding, was born in London in 1843, and educated at Trinity Hall, Cambridge, where he achieved the triple distinction of being senior legalist in the law tripos, president of the Union and stroke of the boat which was head of the river. In 1866 he made a voyage round the world, beginning with the United States, and visiting New Zealand, Australia, Ceylon, India and Egypt. The impressions gained on these travels left him, he said, "with a conception, however imperfect, of the grandeur of our race, already girdling the world, which it is destined, perhaps, to overspread." The book in which he described his travels, *Greater Britain* (1868), gave a great impulse to a sane and reformed imperialism. All his life Dilke was a true imperialist. For him there was no incompatibility between imperialism and extreme radicalism. He became a prominent Liberal politician, as M.P. for Chelsea (1868-86), under-secretary for foreign affairs (1880-82), and president of the local government board (1882-85). In 1871-72 Dilke represented the extreme radical party in England. There was no great love for the Crown, for the Queen's retirement of ten years was a cause of discontent, and he attacked the expense of royalty, in particular the dowries voted for the Queen's children. He was a theoretical republican, and on various occasions in public speeches put the case for republicanism. His own attitude was the reverse of revolutionary. As he said himself, "To think and even to say that monarchy in western Europe is a somewhat cumbersome fiction is not to declare oneself ready to fight against it on a barricade." During these years he says himself he was nearly subjected to physical and really subjected to moral martyrdom, and it is a fact that on one occasion at least nothing but his own imperturbable courage saved his life. Nevertheless, within a few years Disraeli could express the opinion that Sir Charles Dilke was the most powerful and influential member among quite young men that he had ever known.

During his first years in the House of Commons he maintained an independent position. Between 1876 and 1880 he became a close ally of Joseph Chamberlain. Gradually, however, he became a force within the Liberal party, and during the Beaconsfield government with Lord Hartington as leader, the task of presenting the case for the opposition fell more and more into his hands. As a result of the Liberal victory of 1880 he and Chamberlain became members of the Gladstone ministry. In 1885 Dilke was chairman at a conference on industrial remuneration attended by all the prominent trade unionists of the day and women representatives of the Protective and Provident League, afterwards to become the Women's Trade Union League. This was symptomatic of his whole attitude towards labour problems. Throughout his life he was an ardent supporter of better conditions for the workers. While he was at the Local Government Board he called attention to the problem of housing, with the result that a Royal Commission sat in 1884 to study the housing of the working

classes. He was associated with the acts legalizing the position of the Trades Unions and limiting the hours of work. He was in favour of legislation to secure a minimum wage and he wished for the representation of labour in the House of Commons. When the Independent Labour Party emerged in 1894 he was asked to be its leader, but refused on the ground that he differed on certain radical points with its views. He therefore remained its candid friend and critic to the end of his life. He was largely instrumental in 1884 in bringing about the party treaty enabling the Franchise Bill to become law. It was at first rejected by the Lords unless accompanied by a redistribution of seats, a principle for which Dilke had long contended. It was eventually passed at the end of 1884 and the Redistribution Bill early in 1885.

"I never knew a man of his age, hardly ever a man of any age, more powerful and admired than was Dilke during his management of the Redistribution Bill in 1885." Such was Sir George Trevelyan's verdict of a man who combined radical principles with an extraordinary authority on foreign affairs and a capacity for working with men of the most varied views when great questions were at stake. Nevertheless, when Dilke left the Local Government Board on June 24, 1885, on the defeat of the Gladstone ministry, he left official life for ever. At this point he was cited as co-respondent in a divorce suit brought by Donald Crawford, Liberal M.P. for Lanark. Mrs. Crawford was the sister-in-law of Dilke's brother Ashton and the proceedings caused great scandal. The case against Dilke was dismissed, but he determined to retire from public life. In 1884 he had become privately engaged to Emilia Frances Pattison (née Strong), the widow of Mark Pattison, herself an accomplished art critic and collector. She was in India when the blow fell. Her reply to the accusation was the publication of her engagement to Sir Charles Dilke in the *Times*, and she married him on October 3, 1885; she died in 1904. Later, Chamberlain overruled his determination to retire from politics, and he was returned for the Forest of Dean in 1892 and for Chelsea once more in 1905. Although his knowledge of foreign affairs and his powers as a critic and writer on military and naval questions were admittedly of the highest order, his official position in public life could not again be recovered. He was marked out in 1885 as the future leader of the Liberal Party in the House of Commons, and there is little doubt that he might have become one of the great foreign ministers of Europe. He possessed a knowledge of the needs and aspirations of foreign countries rare among his contemporaries, and a definite policy to be pursued irrespective of party politics and the rise and fall of ministers. His military writings are *The British Army* (1888), *Army Reform* (1898) and, with Spenser Wilkinson, *Imperial Defence* (1892). On colonial questions he wrote with equal authority. His *Greater Britain* (2 vols., 1866-67) reached a fourth edition in 1868, and was followed by *The Present Position of European Politics* (1887), *Problems of Greater Britain* (2 vols., 1890) and *The British Empire* (1899).

Emilia Frances, Lady Dilke, his second wife, was the author of a number of books, the most important being the studies on *French Painters of the Eighteenth Century* (1899) and three subsequent volumes on the architects and sculptors, furniture and decoration, engravers and draughtsmen of the same period, the last of which appeared in 1902. A posthumous volume, *The Book of the Spiritual Life* (1905), contains a memoir of her by Sir Charles Dilke. (E.F.M.-S.)

S. Gwynn and G. M. Tuckwell, *Life of Sir Charles Dilke* (2 vols., 1917). Also published in abridged form by G. M. Tuckwell (1925).

DILL (*Anethum graveolens*), an annual or biennial herb of the family Umbelliferae, native to the south of Europe, Egypt and the Cape of Good Hope. It resembles fennel in appearance. The leaves are used in soups and sauces and, as well as the umbels, for flavouring pickles. The fruits are employed for the preparation of dill water and oil of dill, they are largely consumed in the manufacture of gin and when ground are eaten in the East as a condiment. Aqua Anethi or dill-water (dose 1-2 oz.) and the Oleum Anethi, almost identical in composition with caraway oil, and given in doses of 1-3 minims, are sometimes used as a carminative and as a vehicle

for the exhibition of nauseous drugs

DILLEN (DILLENIUS) **JOHANN JAKOB** (1687-1747), English botanist, was born at Darmstadt and educated at the university of Giessen, where he printed in 1719 his *Catalogus plantarum sponte circa Gissam nascentium*. In 1721 he came to England, and in 1724 published a new edition of Ray's *Synopsis stirpium Britannicarum*. In 1732 appeared *Hortus Dillhemensis*, a catalogue of the rare plants growing at Dillham, Kent, for which Dillen himself executed 417 plates, and it was described by Linnaeus as *opus botanicum quo absolutus mundus non vidit*. In 1734 he became professor of botany at Oxford. Dillen, who wrote *Historia muscorum* (1741), died at Oxford on April 2, 1747.

For an account of his collections preserved at Oxford, see *The Dillman Herbaria*, by G. Clardge Druce (Oxford 1907).

DILLENBURG, a town of Hesse Nassau, Prussia, Germany, in wooded country, on the Dill, 25 mi N.W. from Giessen on the railway to Troisdorf. Population 6,470. On an eminence above it are the ruins of the castle of Dillenburg, founded by Count Henry the Rich of Nassau, about the year 1255, and the birthplace of Prince William of Orange (1533). It has a chamber of commerce. Its industries embrace iron works, bronze works, colour works, tanneries and the manufacture of cigars. Owing to its beautiful surroundings Dillenburg has become a favourite summer resort.

DILLENIACEAE, a family of dicotyledonous plants, chiefly ligneous species and mostly trees, shrubs or vines. The group is largely tropical, 11 genera and about 300 species being recognized. The large genera are *Tetracera* with 30 or more species, *Davilla* of tropical America, with about 35 species, *Dolichocarpus* also of tropical America, 20 species, *Hibbertia*, largely Australian, with at least 110 species, *Wormia* with 35 or more species and *Dillenia* with 20 species, but with very large showy flowers and characteristic of the Indo-Malayan region.

For a treatment of the genera see E. Gilg and E. Weidemann, "Dilleniaceae," in Engler and Prantl, *Die Natürlichen Pflanzenfamilien*, ed. 2, vol. 21, pp. 7-36, fig. 1-20 (1925).

DILLEN, JULIEN (1849-1904), Belgian sculptor, was born at Antwerp June 8, 1849, son of a painter, and died at St. Gilles, near Brussels, Dec. 24, 1904. He studied under Eugène Simonis at the Brussels Academy of Fine Arts. In 1877 he received the *prix de Rome* for "A Gaulish Chief taken Prisoner by the Romans," and from this time onward executed a number of important sculptures for the principal towns of Belgium and for the Belgian Government. Perhaps the most famous of these is the group "La justice entre la clemence et le droit," in the Palais de Justice at Brussels.

DILLINGEN, a town of Germany in the *Land* of Bavaria, on the left bank of the Danube, 25 mi N.W. from Ulm by rail. Population 6,220. Dillingen became the residence of the bishops of Augsburg, was taken by the Swedes in 1632 and 1648, by the Austrians in 1702 and on June 1, 1800 by the French. In 1800, it passed to Bavaria. Its principal buildings are an old palace of the bishops of Augsburg, now government offices, a royal gymnasium, a Capuchin monastery and a Franciscan convent. The university, founded in 1549, was abolished in 1804. The inhabitants are engaged chiefly in cattle rearing and the cultivation of corn, hops and fruit. In the vicinity is the Karolinen canal which cuts off a bend in the Danube between Lauingen and Dillingen.

DILLMANN, CHRISTIAN FRIEDRICH AUGUST (1823-1894), German orientalist and biblical scholar, was born at Illingen on April 25, 1823. In 1853 he became professor extraordinary (at Tübingen), and subsequently professor of philoso-

DILL (*ANETHUM GRAVEOLENS*) AN AROMATIC PLANT VALUED FOR FLAVOURING AND FOR ITS MEDICINAL PROPERTIES.

At left is an enlarged drawing of fruit of Dill.

phy at Kiel (1854), of theology at Giessen (1864) and Berlin (1869). He died on July 4, 1894. Dillmann's chief works are the *Book of Enoch* in Ethiopic (1851, German, 1853), the first part of the Ethiopic bible, *Octateuchus Aethiopicus* (1853-55), *Grammatik der aethiopischen Sprache* (1857, Eng. trans. 1907), the *Book of Jubilees* (1859), another part of the Ethiopic bible, *Libri Regum* (1861 and 1871), *Lexicon linguae aethiopicae* (1865), *Chrestomathia aethiopica* (1866). His *Commentum cum Hiob* (1869) stamped him as one of the foremost Old Testament exegetes. His renown as a theologian was mainly founded by the series of commentaries on other Old Testament books including *Genesis*, *Exodus* and *Leviticus*, *Numeri*, *Deuteronomium* and *Josua*, and *Jesaja*. In 1877 he published the *Ascension of Isaiah* in Ethiopic and Latin, and in 1895 *Vorlesungen über Theologie des Alten Testaments* appeared.

See W. Baudissin, A. Dillmann (Leipzig, 1895).

DILLON, ARTHUR RICHARD (1721-1807), French archbishop, was the son of Arthur Dillon (1670-1733), an Irish general in the French service. He was born at St. Germain, held many important preferments and in 1763 became archbishop of Narbonne, and in that capacity, president of the estates of Languedoc. He carried out many works of public utility, bridges, canals, roads, harbours, etc., had chairs of chemistry and of physics created at Montpellier and at Toulouse, and tried to reduce poverty. In 1787 and 1788 he was a member of the Assembly of Notables called by Louis XVI, and in 1788 presided over the assembly of the clergy. Refusing to accept the civil constitution of the clergy, Dillon emigrated to Coblenz in 1791. He lived in London until his death in 1807, never accepting the Concordat.

See L. Audibert, *Le Dernier Président des États du Languedoc*, Mgr Arthur Richard Dillon, archevêque de Narbonne (Bordeaux, 1868), L. de Lavergne, *Les Assemblées provinciales sous Louis XVI* (Paris, 1864).

DILLON, JOHN (1851-1927), Irish nationalist politician, was the son of John Blake Dillon (1816-1866), who sat in parliament for Tipperary, and was one of the leaders of "Young Ireland." John Dillon was educated at University College, Dublin, and afterwards qualified as a surgeon. He entered parliament in 1880 as member for Tipperary, and was at first an ardent supporter of C. S. Parnell, whom he accompanied in his tour of the United States in that year. In August he delivered a bitter speech on the Land League at Kildare, he advocated boycotting, and was arrested in May 1881 under the Coercion act, and again after two months of freedom in October. In 1883 he resigned his seat for reasons of health, but was returned unopposed in 1885 for East Mayo, which he continued to represent. He was one of the prime movers in the famous agrarian "plan of campaign" (see *IRELAND, History*). Dillon was compelled by the court of queen's bench on Dec. 14, 1886, to find securities for good behaviour, and in June 1888 under the provisions of the new Criminal Law Procedure bill he was condemned to six months' imprisonment. He was released in September, and in the spring of 1889 sailed for Australia and New Zealand, where he collected funds for the Nationalist party. On his return he was again arrested, put, being allowed bail, sailed for France in a fishing-boat with W. O'Brien, and thence to America. He returned to Ireland by way of Boulogne, where he and W. O'Brien held long and intensive conferences with Parnell. They surrendered to the police in February and on their release from Galway gaol in July declared their opposition to Parnell. After the expulsion of T. M. Healy and others from the Irish National Federation Dillon became the champion (Feb. 1896). His early friendship with O'Brien gave place to disagreement but the various sections of the party were ostensibly reconciled in 1900 under Redmond's leadership. In the autumn of 1896 he arranged a convention of the Irish race, which included 200 delegates, from various parts of the world. In 1897 Dillon opposed in the house the diamond jubilee address to Queen Victoria on the ground that her reign had not been a blessing to Ireland. He was suspended on March 20 for violent language addressed to Joseph Chamberlain.

In 1907 he advised Irishmen in England to vote Liberal at the general election and began to support the Liberal government.

in its Irish measures, notably the Land bill, although in his earlier days he had opposed ameliorative measures as likely to defer Home rule. In the crisis of 1912 over the Better Government of Ireland bill Dillon urged that Nationalists should concentrate on the attack against the house of lords. In July 1914 he was invited by King George V to accompany Redmond to the Buckingham Palace conference which attempted to settle the Irish controversy, when his attitude is said to have been stiffer than Redmond's.

When war broke out, he immediately placed his whole influence behind the British government, speaking in this sense at the meeting in the Dublin Mansion House on Sept. 25, 1914. He took an active part in recruiting but steadily opposed the extension of conscription to Ireland which would, he was convinced, merely strengthen the Sinn Féin movement. He succeeded Redmond as leader of the Nationalist party, and at the General Election of Dec. 1918 he shared the general obliteration which overwhelmed the party. He died in London on Aug. 4, 1927, and was buried in Glasnevin cemetery, Dublin, by the side of his wife (d. 1907), a daughter of Justice Mathew.

DILLON, a city of southwestern Montana, U.S., on the Beaverhead river, the Union Pacific railroad and federal highway 91, the county seat of Beaverhead county. The population in 1950 was 3,079, in 1940 it was 3,014 by the federal census. It has a picturesque location on a plateau 5,200 ft above sea level, surrounded by mountain peaks. It is the hub of an extensive live stock, agricultural and mining (gold, silver, lead and copper) region. Dillon was settled about 1880 and incorporated in 1885, and is the seat of the Western Montana College of Education, which was established in 1893.

DILTHEY, WILHELM (1833–1911), German philosopher, was born on Nov. 19, 1833, at Diebrich and died on Oct. 1, 1911, at Seis, near Bolzano. He was successively professor in Basle (1866), in Kiel (1868), in Breslau (1871), and in 1882 succeeded Lotze in Berlin. As a supporter of positive Idealism, Dilthey regards the external world as a representation arising out of pure experience, will as well as thought being a factor of knowing and of self consciousness. His empirical tendency also appears in his historical approach to philosophy. His chief writings are *Leben Schleiermachers* (1870), *Einführung in die Geisteswissenschaften* (1883), *Das Erlebnis und die Dichtung* (1905), *Die Jugendgeschichte Hegels* (1905), *Systematische Philosophie* (1907), *Der Aufbau der geschichtlichen Methode in den Geisteswissenschaften* (1910), *Weltanschauung u. Analyse des Menschen seit Renaissance und Reformation*, 2 vols. (1921).

See E. Spranger, *Wilhelm Dilthey* (1922).

DILUVIUM, a term in geology for superficial deposits formed by floodlike operations of water, and so contrasted with alluvium (*g v*) or alluvial deposits formed by slow and steady aqueous agencies. The term (Lat. for "deluge," from *diluvio*, to wash away) was formerly given to the "boulder clay" deposits, supposed to have been caused by the Noachian deluge. In this sense it still lingers on the continent of Europe, but it has disappeared from British geological literature.

DIME, the tenth part, the tithe paid as church dues, or as tribute to a temporal power. In this sense it is obsolete, but is found in Wyclif's translation of the Bible—"He gave him dimes of all things" (Gen. xiv, 20). A dime is a silver coin of the United States, in value 10 cents (English equivalent about 5d), or one-tenth of a dollar, hence "dime-novel," a cheap sensational novel, a "penny dreadful", also "dime-museum" and "dime-store."

DIMENSION, a term used in geometry to denote a magnitude measured in a specified direction, as, for instance, along a diameter or a principal axis or an edge. A point is said to be without dimension, a line has the one dimension of length, a surface has the two dimensions of length and breadth, while a solid has the three dimensions of length, breadth and thickness. Since the lengths of lines, the areas of surfaces and the volumes of solids are represented respectively by linear, quadratic and cubic algebraic expressions, the term dimension has been carried over into algebra. Thus quadratic, cubic, biquadratic algebraic expressions or equations are said to be respectively of two, three, four dimen-

sions. Similarly, the term dimensions is used in mechanics with reference to the units of time, length and mass and various derived units (see DIMENSIONAL ANALYSIS), and it occurs likewise in many other parts of physics, notably in the theory of electricity and magnetism (see PHYSICAL UNITS).

The fundamental descriptive proposition concerning space, as we are accustomed to it in experience is that space is a continuum (a continuous or unbroken distribution of points) having three dimensions. The intuitive basis of this proposition may be elucidated as follows. If on a curve (or line) we mark certain points (elements without dimension) we separate the curve into parts bounded by the points in such a way that we cannot pass along the curve from one part to another without encountering and passing over one of these marked points. Since the curve may be separated into parts by elements without dimensions it is itself said to be a figure having one dimension. But a surface cannot be thus separated into parts by marking isolated points on it, for, in going from one place to another on the surface, we can always avoid passing over these marked points by going around them. If we draw in the surface a suitable closed curve (a figure of one dimension) then the surface is separated into parts in such a way that we cannot move over the surface from one part to another without encountering and passing over a point on the curve. Since a surface can not be separated into parts by points (figures without dimension) but can be separated into parts by a suitable figure of one dimension, we say that a surface itself has two dimensions. Similarly space cannot be separated into parts by isolated points or curves or both taken together, while it can be so separated into parts by means of a closed surface (a figure of two dimensions). For this reason we say that space has three dimensions. Thus, according to Henri Poincaré (*Dernières Pensées*, Flammarion, Paris, 1917, pp. 61 ff.), is the fundamental qualitative ground for ascribing three dimensions to the usual space of experience.

The mathematician introduces three co ordinates to represent the points of ordinary space and much of his analysis of its properties is carried out algebraically. Now the algebraic analysis is competent to deal with sets of any number n of co ordinates. Thus algebraic geometry leads readily to the conception of spaces of any number n of dimensions, and these have been extensively treated, though no one has a lively mental picture of spaces having more than three dimensions. Popular interest in these higher spaces (as opposed to the interest of mathematicians in them) has been centred principally around the concept of the "fourth dimension." But the number of dimensions of these higher spaces is unlimited, and, in fact, several kinds of space with an infinite number of dimensions have been investigated.

That the higher spaces may be given a concrete representation in terms of experience is shown by the fact that the totality of straight lines in our usual space of three dimensions constitutes a veritable space of four dimensions (see PROJECTIVE GEOMETRY). This arises from the fact that four independent co ordinates are necessary to define completely the position in space of a line of unlimited extent. Therefore a geometry in which the elements are the lines of ordinary space is a geometry of four dimensions (R. D. CA).

DIMENSIONAL ANALYSIS The principal use of dimensional analysis is to deduce from a study of the dimensions of the variables in any physical system certain necessary limitations on the form of any possible relationship between those variables. The method is of great generality and mathematical simplicity. The name dimensional analysis is comparatively new, Lord Rayleigh, one of the earliest and principal exponents of the method, called it the principle of similitude. In earlier editions of this *Encyclopædia* it was treated under the heading UNITS, DIMENSIONS OR

This method is not capable of completely determining the unknown functional relationship. In the simplest cases it can give everything except a numerical factor of proportionality, for example, it can show that the time of swing of a simple pendulum is independent of its mass and proportional to the square root of its length but cannot determine the constant of proportionality.

In more complicated cases, where there are a larger number of variables, it can show that the variables must enter the function in certain definite combinations, thus reducing the number of the undetermined functional relations. Perhaps its most important use is in connection with problems so complicated that not only may an exact solution by purely mathematical methods be impossible, but also it may be impossible even to give a precise and detailed formulation of the fundamental equations from which the solution is to be found. Many problems of aeroplane or ship design are of this nature. In these cases a knowledge of the necessary limitations on any possible functional relationship makes it possible to cover completely the range of all possible experimental relationships with a much smaller number of experiments than would be necessary otherwise. In this capacity it now receives the widest application in engineering. Other uses of dimensional analysis are as a simple check, against error in writing out equations or their solutions, in changing units from one system to another, and in theoretical investigations in making preliminary orienting surveys to explore promising lines of attack.

The methods of dimensional analysis depend to an important extent on the properties of the systems of measurement in ordinary scientific use and presuppose the use of such systems. These systems are subject to certain definite limitations. It is a matter of extensive past experience that all the physical systems ordinarily encountered can be completely described in terms of measurements of the restricted and conventional scientific sort. It is this past experience, the mere existence of which is not always obvious to an uncritical glance, that is capitalized in obtaining the results of dimensional analysis. For, since the system of measurement is subject to limitations and has definite properties, the fact that it can be applied to such a wide variety of situations implies the possession of certain properties by those situations, it is these properties which are brought explicitly to light by dimensional analysis. In respect to this degree of dependence on past experience dimensional analysis differs from no other scientific enterprise, for it is never possible to obtain factual information about any concrete physical situation by pure ratiocination, but any factual information which emerges in the final mathematical formula had to be explicitly inserted into the mathematics at an earlier stage.

Since it is basic to everything that follows, we begin our detailed argument with an examination of such properties of the systems of scientific measurement as are necessary for our purpose. Many different systems of measurement are in general possible, the desirability of any particular system depending on the purpose in hand and on the physical system to which the measurement is applied.

The primary purpose of a system of measurement may be taken to be precise description. In practice one method of securing precision has proved to be so overwhelmingly superior to any other that it alone survives in serious scientific usage, this is by the specification of numbers. Measurement, then, in a very broad sense means description by the assigning of numbers. Given a concrete physical system, it is possible to assign various numbers to it by performing various sorts of physical operation upon it. The number obtained by any particular kind of physical operation constitutes a particular kind of measurement. Different aspects of the system are dealt with by employing different sorts of measuring operation. If one were dealing with only a single isolated physical system a high degree of arbitrariness would be permissible in the measuring operations by which the system is described. In practice, however, a large part of this arbitrariness disappears because of the fact that we desire to deal with large numbers of physical systems. This leads to the requirement not only that the physical operations back of the measurements be easily applicable to the widest variety of systems, but also that they be such that it is possible to express in relatively simple mathematical terms correlations between the results of measurements on different systems. The discovery of measuring operations which satisfy these requirements came only after hundreds of years of experience and experimenting, and demanded a wide acquaintance with the factual content of our environment.

The requirements of convenient application to many systems

and of adaptability to mathematical correlation are not sufficient, however, to determine uniquely the measuring operations but a great deal of flexibility remains. As a matter of fact, a wide variety of systems and methods of measurement are in scientific use today.

We now consider in some detail the properties of the systems of measurement in actual physical use, starting from the general point of view that a physical measurement is a number obtained by a particular kind of physical operation. The sort of measurement that it is, is determined by the sort of operation that it is. **Length, Weight and Time**—Consider, for example, length. We may define this as the number obtained by the operation of applying a metre stick to successive positions on a body, counting the number of applications, and reading the fractional part from the divisions inscribed on the metre stick. This procedure is applicable to a wide variety of physical systems. From the point of view of maximum precision, once having defined length by this single definite procedure, the name length should be applied only to numbers obtained by this one procedure. In practice, however, there prove to be whole families of operations giving numbers which are either undistinguishable from the numbers given by the defining operation or else are related to them by a constant of proportionality so that in practice the term length is given the extended meaning of a number obtained by any one of the family of operations.

The family of operations which is at present accepted as defining length may be divided into various subfamilies. Some of these subfamilies involve drastic physical changes in the measuring operations such, for example, as measuring lengths by optical methods of triangulation, or by counting interference fringes. It is particularly necessary to subject the equivalence of widely different types of operation to fresh experimental check whenever the field of application is extended. Other subfamilies of operations, however, may be specified with very slight verbal changes. By far the most important of these involve the use of some fundamental measuring stick other than the one of the fundamental definition. For example, instead of specifying the metre stick as basic to the operations of measuring length, we may substitute a foot rule, keeping all the other verbal instructions the same. Strictly, it requires experimental confirmation to show that the verbally specified operations are still physically performable when foot rule is substituted in the specifications for metre stick. The recognition that the operations are performable with either is so deeply ingrained in all our experience that we usually do not realize, unless we stop to think about it, that we are saying something about the structure of the world when we say that a length may be measured either with a metre stick or with a foot rule. Dimensional analysis involves some of the consequences of the world being constructed in this way.

We designate the results of operating according to the specifications for measuring length as length in metres or length in feet. An inspection of what we do now shows that there is a simple invariant relation between the two sorts of length. The metre stick itself is an object whose length in feet can be determined, and similarly the length of the foot rule may be measured in metres. We express this by saying so many feet make a metre or a certain fraction of a metre makes a foot. Due consideration of this, together with an examination of the details of any concrete measuring operation, shows that the ratio of the length of any concrete object in metres to its length in feet is a constant, independent of the object, and equal to the number of metres in a foot or the length of the foot in metres. A generalization of this consideration evidently applies to measurement of length with any other primary standard of length, parasang, verst or what not. An immediate mathematical consequence of this application is that the ratio of the lengths, that is, the ratio of the length numbers, of any two concrete objects, both measured with the same primary standards, is the same, independent of what primary standard is used. We may express this by saying that relative length has absolute significance. This is only a special case of a general requirement exacted of any method of making any sort of physical measurement which is to be accept-

able for scientific use, namely the requirement of the absolute significance of relative magnitude

The possibility of maintaining the requirement of the absolute significance of relative magnitude has to be determined by fresh examination of the details of the measuring process for each new kind of measurement with which we are concerned. For instance, the measurement of weight is obviously an entirely different sort of measurement from the measurement of length. The operations for weighing may be specified in terms of an equal arm balance. It is not the place here to expand the details of the weighing process. It is evident, however, that certain of the same general results hold for measuring weights as for measuring lengths. We may measure weights in terms of different standards of weight. The weights of the same object in terms of different standards bear a fixed ratio depending on the relative magnitude of the standards, and the ratio of the weights of two different concrete objects is independent of the standard of weight. The requirement of the absolute significance of relative weight is satisfied. Detailed examination shows that the fact that it is satisfied involves the physical law of the conservation of weight—the total weight of all the little weights into which we cut up a standard in order to make a new standard is the same as before it was cut up. There is no immediate, obvious connection between the physical property of conservation of weight and the geometrical properties of lengths placed end to end. We could not have predicted the possibility of the absolute significance of relative weight from the known absolute significance of relative length, but a fresh appeal to experiment is necessary.

Equally fundamental with length and weight is the measurement of time. The physical operations are again basically different: time does not recur, but we pass over it only once. We cannot ask whether two intervals of time are equal by placing one interval in juxtaposition with another and comparing them, as we do two lengths or two weights. The operations are different: they are performed with clocks, according to rules which we shall not attempt to formulate in detail. However, the same results that we have found previously carry over to the new situation. In particular, we can specify operations by which the same interval may be measured in terms of different standard intervals. The ratio of the time numbers obtained for any specified time interval by operating with different standard intervals is always the same and depends only on the standards. Furthermore, the relative value of any two different concrete intervals is independent of the interval adopted as fundamental, or in other words, the requirement of absolute significance of relative magnitude is still met. A proof of this can be given by observation of the details of the measuring process with clocks, and involves the properties of the angles swept over by the hands of the clock. There is no immediate connection with the physical situation involved in the absolute significance of relative length or of relative weight.

The measurements of length, weight (or mass) and time are similar in that the operations make direct reference by one physical process or another to standards of length, mass or time. This involves the existence of different physical operations for mass, length and time analogous to the mathematical operation of addition for numbers. Furthermore, other properties of these physical operations are involved, for the resulting mass numbers, or length numbers, or time numbers are combinable according to the commutative or associative rules for mathematical addition. These requirements are obviously definitely restrictive, not every sort of simple physical operation satisfies them, for example, successive rotations through a finite angle about different axes. It required long experience to find such operations. There are still other sorts of physical operations which may be made the basis of other sorts of physical measurement which have similar properties. For example, forces may be measured by direct comparison with a standard force given by a definite deflection on a spring balance, and the physical operation for the addition of forces exists and consists in simply applying two spring balances in parallel to produce twice the force.

Secondary Measurements—When we make a measurement in this way by direct reference to some concrete standard by means of a physical addition law, we may be said to be making a primary measurement. Most physical measurements are, however, more complicated, and are compounded of simple primary measurements. Such may be called secondary measurements. A simple example is velocity, which is ordinarily defined as the quotient of distance by time, or more exactly the quotient of a distance number by a time number. To measure the velocity of any concrete moving object, we measure the time required by it to traverse a known measured distance, and divide the distance by the time. The distinction between primary and secondary measurement is not absolute, in some cases either method may be used. An example is force. We have indicated above how to measure force as a primary quantity by reference to a spring balance. If we wish to define it as a secondary quantity, we may utilize Isaac Newton's first law of motion, defining force as equal to mass times acceleration. In this case we obtain the force on any body by measuring the mass of the body and its acceleration, which in turn is obtained by measuring the change of velocity in a known time interval, the velocities themselves being obtained from measurements of distance and time. That is, when force is defined as a secondary quantity it is measured by making certain primary measurements (mass, length and time), which are then combined by mathematical rules. Other instances may be given of the possibility of either a primary or a secondary definition. Thus, velocity may be measured as a primary quantity by methods which have been described in detail. Or density, which ordinarily is treated as a secondary quantity and defined as mass divided by volume, may be treated as a primary quantity. In this latter case the difficulties of the necessary physical manipulations would obviously be prohibitively great except when dealing with gases at comparatively low pressures. Whether a given quantity is to be treated as primary or secondary is to a certain extent a matter of convenience, depending on the particular situation. In certain problems, for example, force is best treated as secondary, while in others more information is obtained by treating it as primary.

A certain aspect of the measurement of secondary quantities, which is significant for our purposes is singled out and specified by giving the dimensional formulas of these quantities. Since the numerical magnitude of any primary quantity changes when the size of the corresponding primary standard is altered, the numerical magnitude of secondary quantities also changes when the size of the primary standards is changed. It is with this aspect that we are chiefly concerned in setting up dimensional formulas. Thus, the dimensional formula of velocity, defined as above, is LT^{-1} , or $[V] = [LT^{-1}]$, where the square brackets denote "dimensions of," and the equation stands for the verbal expression "the dimensions of velocity are the dimensions of length divided by time. This is merely a shorthand statement for the number which, in the given system of measurement, measures the velocity of any concrete object, is obtained by multiplying the number which measures some distance associated with the object by the reciprocal of another number which measures some time associated with the object. In future applications the square brackets will usually be omitted as unnecessary. In the formula, T^{-1} indicates the reciprocal of a number obtained by the process for measuring T , the exponent -1 is to be associated with the number, not with the T , that is, the existence of another physical operation, the analogue of the mathematical operation of taking the reciprocal, is not involved or implied by this notation. The dimensional formula is obviously only a partial statement; it does not, for example, contain the detailed specifications for associating the measurements of length and time. The dimensional formulas apply to the primary quantities as well as secondary quantities. For instance, we denote the dimensions of length by L . The significance of this is that the number which measures a length is obtained by a definite physical procedure and the L recalls this procedure. Whenever L occurs in a dimensional formula, the connotation is that a number was obtained by the procedure specified for measuring length. By recalling this pro-

cedure we are in a position to find how the numerical magnitude changes when the size of the standard changes.

Dimensional Formulas—Let us examine other examples of dimensional formulas. What is the dimensional formula for acceleration? By what procedure do we obtain the number which measures acceleration? This is given by definition: acceleration is change of velocity in a given time so that the first result would be, $[\text{Acceleration}] = [(V_1 - V_2)/T]$, where V_1 and V_2 apply to the final and initial velocities. In use this expanded dimensional formula is at once contracted: the first contraction is to write $[\text{Acc}] = [V T^{-1}]$. That is, our purpose does not demand that we continually remind ourselves that a certain number was obtained by taking the difference of two velocities, but it is sufficient to remember only that the procedure for obtaining velocity entered our operations. This contraction obviously implies a very important restriction, which indeed is contained in the definition, we must measure the initial and final velocity in the same system of units. The reason that the contraction of the dimensional formula is permissible is that under the conditions the difference of two concrete velocities changes by the same factor as do each of the velocities separately when the fundamental units are changed. The dimensional formula for acceleration may now be contracted further by writing $[\text{Acc}] = [L T^{-2}]$. Here we have expressed the fact that the number measuring a velocity is obtained by dividing a length number by a time number. A further contraction at once suggests itself to combine the two T^{-1} 's into a single term, writing $[\text{Acc}] = [L T^{-2}]$. But this contraction obviously involves another implication that the unit of time used in measuring velocity is the same as the unit of time used in measuring change of velocity. If this is not the case, we have left out a factor which determines how the number changes when we change the fundamental units. In practice, hybrid units are not uncommon. The performance of the brakes of an automobile might be described by saying that the car is brought to rest from a velocity of 30 mi per hr in 5 sec. Acceleration measured in this way is not covered by the dimensional formula above.

In all our analysis it is expressly supposed that all measurements of secondary quantities are such that the same primary units are consistently used at all stages of the measuring process. Under these restrictions we are justified in contracting $T^{-1} T^{-1}$ to T^{-2} because the number obtained by multiplying the reciprocal of a number obtained by measuring a concrete time interval by the reciprocal of another number measuring another concrete time interval, changes by the same factor as the product of the two numbers measuring a concrete time interval when the fundamental unit of time is changed. It appears, in general, that addition or subtraction of simple dimensional symbols is without significance for our purposes and may be ignored (as in the formulas for acceleration), and products may be combined by the simple algebraic rules for exponents.

The dimensional formulas of the simple secondary quantities, velocity and acceleration, examined thus far are of the same simple type that is, products or powers of the primary quantities. This is true of a number of other such quantities; no given illustration. The dimensions of force, defined as mass times acceleration, are $M L T^{-2}$; the dimensions of momentum, defined as mass times velocity, are $M L T^{-1}$; the dimensions of work or energy, defined as the product of force and distance (parallel to the force), are $M L^2 T^{-2}$; the dimensions of moment of force, defined as the product of force and distance (perpendicular to force), are also $M L^2 T^{-2}$; and the dimensions of viscosity, defined as force per unit area per unit velocity gradient, are $M L^{-1} T^{-1}$. All these secondary quantities are seen by inspection to have the same important property which, as we have seen, is enjoyed by the primary quantities—that is, the property of absolute significance of relative magnitude. This property follows at once from the construction of the dimensional formulas as products of powers.

The Property of Absolute Significance of Relative Magnitude—It is easy to give a formal proof that any quantity whose dimensional formula is composed of products of powers

has the property of absolute significance of relative magnitude. It will be sufficient to consider systems in which the fundamental quantities are taken as mass, length and time—the extension to other systems involving only trivial modifications.

Consider any secondary quantity of the specified type, the dimensional formula of which may be written as $M^a L^b T^c$. Consider two concrete examples measured in a certain system of concrete units, and denote by $M_1^a L_1^b T_1^c$ and $M_2^a L_2^b T_2^c$ the numbers obtained by combining the component measures of mass, length and time in the way specified by the definition of the secondary quantity. Then the ratio of the two magnitudes is $M_1^a L_1^b T_1^c / M_2^a L_2^b T_2^c$. Now consider a second system of measurement in which the unit of mass is smaller in the ratio μ than in the first system, the unit of length is smaller in the ratio λ , and the unit of time is smaller in the ratio τ . Then the number which measures any concrete mass will be larger by the factor μ in the second system than in the first, and similarly for the numbers which measure length and time. Hence, the numerical magnitude of the secondary quantity for the first concrete example will now be $(\mu M_1)^a (\lambda L_1)^b (\tau T_1)^c$, and for the second concrete example $(\mu M_2)^a (\lambda L_2)^b (\tau T_2)^c$. On taking the ratio of these, the μ , λ , and τ cancel, leaving the same result as at first. That is, the ratio of the numerical measures of any two concrete examples is independent of the size of the fundamental units for secondary quantities constructed on the scheme of products of powers of the primary quantities: this is what is meant by absolute significance of relative magnitude. The converse is also true, the dimensional formula of any quantity which satisfies the principle of the absolute significance of relative magnitude is constructed of products of powers of the primary quantities (the proof will not be given here).

The property of absolute significance of relative magnitude has proved to be of such very great convenience in application that no secondary quantities are in present scientific use which do not satisfy this principle, and whose dimensional formulas therefore are not products of powers. It is an express presupposition of all the following discussion that the dimensional formulas of all quantities have the form of products of powers. The formulas of primary quantities already have this form identically.

The Formula as Definition—The dimensional formula may serve as a signpost suggesting the underlying definition. There is obviously no rigorous and exact correspondence between the dimensional formula and the definition, as shown by the example above in which energy and moment of force have the same dimensions. However, in a great many practical cases the dimensional formula permits a decision between conceivable alternatives and is therefore useful as a mnemonic device. In fact it is not uncommon for the system of measurement to be specified by listing the dimensional formulas of various quantities. This method is much used with reference to the various systems of electrical units. Such a listing of dimensional formulas is often entirely adequate, but obviously it presupposes an initial specification more formal and more precise.

Assume that we have developed a system of physical measurement, with measuring procedures and fundamental units specified, secondary quantities defined and all dimensional formulas written out. We address ourselves to apply this system of measurement to some physical system or set of systems. Our problem is to find relationships between various measurable quantities. We proceed at first on a purely empirical basis, by plotting certain quantities or combinations of quantities against others to find whether the points lie on curves or surfaces. The existence of such curves or surfaces means a relationship, having found such, we then try to find a mathematical equation which shall reproduce the curve or surface within experimental error. Having found this we believe that we have acquired the power to predict the results of any new experiment or measurement on the system, because if we substitute into the equation (or plot on the graph) an independent variable as yet not realized experimentally, the corresponding dependent variable as determined by the equation or the graph will correspond to what we will find when we make the experiment. Of course there is no

logical necessity in this. The assumption is made in virtue of our past experience that interpolation is usually smooth.

Consider a very simple example. We use for our fundamental primary units the pound, the foot and the second, and make application to all systems of weights falling freely from rest under the action of gravity near the surface of the earth. We collect data for the widest range of conditions and find that all our observations satisfy certain equations, namely

$$\text{Distance of free fall} = 16 \times (\text{square of time of fall})$$

$$\text{Velocity of fall} = 32 \times (\text{time of fall})$$

These equations are a complete and adequate description in the sense that given the time or distance or velocity we can predict what the other two quantities will be for any new experiment in the future or recall what they were at any time in the past. But this may not satisfy us, we notice that there has been an element of arbitrariness in our procedure in that we chose the pound, foot and second as fundamental units. We might have chosen the gram, centimetre and minute as fundamental. If we had, would we have to make our physical measurements all over again? We suspect that we would not, and that there must be some relation between measurements in the two systems, because each system is constructed on the same pattern, and the principle of absolute significance of relative magnitude holds for measurements in the two systems. In fact, substitution of the concrete values for two examples shows that for any other such system satisfying the principle of absolute significance of relative magnitude we must have

Distance of free fall is proportional to square of time of fall

Velocity of free fall is proportional to time of fall

The factors of proportionality obviously depend on the system of measurement. We now have the answer to our question given a relationship between quantities in any scientific system of measurement, we can at once find corresponding relationships in any other system for which the principle of absolute significance of relative magnitude holds. The change from one system to the other is to be made by changing certain factors of proportionality. Precisely how shall we change the factor of proportionality? We have seen how to change the numerical value of a physical quantity given its dimensional formula. Can we perhaps assign dimensional formulas to our factors of proportionality in our present problem? Inspection shows at once that if we assign to the factor in the first equation the dimensions of LT^{-2} and to the factor in the second equation the dimensions of VT^{-1} our problem is solved, because through the compensatory action of the factor of proportionality the numbers which we substitute into the equation when we measure in pounds, feet and seconds combine so as to give identically the same final result as when we measure in grams, centimetres and minutes.

The Dimensional Constant.—We see then that we may pass back and forth between equations for different systems of measurement, provided the systems satisfy the principle of absolute significance of relative magnitude, by the device of assigning suitable dimensions to various factors of proportionality. A factor of proportionality which varies when the units change according to a scheme which can be specified by giving to it a dimensional formula is called a dimensional constant.

The equations for the falling body, written with the appropriate dimensional constants, obviously hold for any system of units in which mass, length and time are taken as fundamental. An equation of this sort, which holds without formal change when the size of the fundamental units changes, is called a complete equation. In the problem of the falling body there are two dimensional constants, one for the first and one for the second equation. We notice, however, that the dimensions of the second constant, VT^{-1} reduce to those of the first constant, when we substitute for V its dimensions LT^{-1} . That is, in this problem we have essentially only one dimensional constant, instead of the two which are given formally by the two equations. What is the significance of this?

The problem of the falling body is a problem over which we have adequate theoretical mastery, it is a problem in mechanics, and the motion of the body can be obtained by an integration

of the equations of motion. We should, therefore, be able to obtain the relations between distance and velocity and time of fall by purely mathematical operations performed on the fundamental equations of motion. An inspection of the nature of any purely mathematical process, such as is involved in solving the equations of motion, shows that if the initial equation is complete the final equation resulting from the mathematical manipulation is also complete. Furthermore, no new dimensional constants can be introduced by any mathematical manipulation. Any dimensional constants in the final result must have been present in the original equations from which the final result was deduced. The equation of motion for a falling body is

$$\text{Acceleration of falling body} = \text{constant}$$

The constant acceleration is usually denoted by g , and it is obviously a dimensional constant because its numerical magnitude changes with the size of the fundamental units. In other words, the fundamental equation of motion contains only one dimensional constant, and any relationships implicit in the equation and deducible by mathematical manipulations can contain only the same constant. Of necessity the dimensional constant in the two empirical equations first written must be the same. In fact, the explicit relations are

$$S = \frac{1}{2}gt^2, \text{ and } v = gt$$

It is obvious that any empirical equation whatsoever expressing a relation between various physical parameters can be written as a complete equation by the device of introducing dimensional constants as factors multiplying each parameter, the numerical values of the constants being so adjusted as to be unity in the original system of units. This device demands as many constants as parameters. However, if the relationship can be deduced theoretically, that is by mathematical manipulation of fundamental equations, which by construction are always complete equations, then the relationship will be complete and will involve only those dimensional constants which enter the fundamental equations. The number of such constants, in general, will be smaller than the number of physical parameters, so that an advantage has been gained as compared with the purely empirical method of treatment.

Scientific achievement has now reached such a state of progress that the nature of the fundamental governing equations is known for practically all situations of ordinary occurrence, so that in these situations we know that there are relationships which can be expressed in the form of complete equations between the physical parameters of the system and certain specifiable dimensional constants, that is, the constants which appear in the fundamental equations.

The II Theorem and Dimensional Homogeneity.—Any mathematical relationship between parameters x_1, x_2, x_3, \dots can be written by a rearrangement in the form of an equation $f(x_1, x_2, x_3, \dots) = 0$. If the physical system to which this equation applies is one of the very large number in which the nature of the fundamental governing equations is understood, then this equation can be so rearranged as to appear to be a complete equation, because it might have been deduced by mathematical manipulation. There are important restrictions on the mathematical form of any complete equation. Dimensional analysis is essentially a study of the restrictions on the form imposed by the requirement of completeness. There is a fundamental theorem here, the so called II theorem, apparently first explicitly enunciated by E. Buckingham, although used implicitly ever since the time of Baron Jean Baptiste Fourier, who was the first to apply dimensional considerations. All the parameters which enter into the functional relationship are given. These will include both physical parameters and dimensional constants, and both physical parameters and dimensional constants are similar in that they have dimensional formulas expressible as products of powers of the fundamental units.

The II theorem states that, subject to an important restriction, the functional relationship must be expressible in such a form that it contains as arguments only such products of powers of the physical parameters and dimensional constants as have zero dimensions in all the fundamental quantities. The restric-

tion is that there be not more than one independent functional relationship between the quantities. The II theorem may be rephrased to express the principle of dimensional homogeneity, which is often taken as the fundamental theorem of dimensional analysis. Let us express the function which satisfies the II theorem, as

$$F(\Pi_1, \Pi_2, \dots) = 0,$$

where the Π 's are the dimensionless products formed from all the parameters. We may solve the equation for one of the arguments, say Π_1 , and express Π_1 in terms of the component parameters, say as $p_1^a p_2^b p_3^c$, and then solve for the first, writing the equation as

$$p_1^a = p_2^{-b} p_3^{-c} f(\Pi_2, \Pi_3, \dots)$$

The function f , having only dimensionless arguments, contains only dimensionless terms. By construction of Π_1 , the dimensions of p_1^a (which stands on the left hand side of the equation) are the same as the dimensions of $p_2^{-b} p_3^{-c}$ which multiplies the f on the right, all the terms of which are dimensionless. Hence, every term on the right hand side has the same dimensions as the single term on the left, or, in other words, the equation expressing the relationship is dimensionally homogeneous.

Attempts have often been made to prove the principle of dimensional homogeneity by vague intuitive arguments. The following is an example "Every equation which expresses an 'essential' physical relation must be independent of the size of the fundamental units, and in such an equation every term must have the same dimensions because it is meaningless to add together terms with different physical dimensions, as for example a length and a time." That such an argument is not valid in general can be seen by considering such equations, for example, as the equation for a falling body $(v - gt) + (s - \frac{1}{2}gt^2) = 0$. This is a true equation, since it is always satisfied whenever the simultaneous values of v , s and t for any falling body are substituted into it, furthermore, it is a complete equation, because it holds without change no matter what the size of the units of length and time. It is, however, obviously not dimensionally homogeneous.

The restriction that there is only one functional relationship is essential to the II theorem and to the principle of dimensional homogeneity. The equation just given obviously falls apart into two equations $v = gt$ and $s = \frac{1}{2}gt^2$. In practice the requirement of only one functional relationship is no essential restriction because we are always interested in reducing the relationships until only one remains. If there should be two relationships, one of the arguments may be eliminated between the two, leaving a single relation between a smaller number of arguments.

The functional relation as it first comes from the pen of the mathematical analyst may not obviously satisfy the II theorem, but some rearrangement may be necessary. The II theorem states that such rearrangement is always possible. This has particular application to the so-called logarithmic constants which often present themselves in thermodynamic analysis.

The II theorem places no restrictions whatever on the form of the functional relationship, the restriction is only on the arguments. The importance of the restriction consists in the fact that the number of possible independent dimensionless arguments is in general less than the full number of physical parameters. The number of experiments necessary to find the form of an unknown function is obviously less if we are dealing, for example, with a function of only one argument instead of with one of three.

Consider a system of measurement in which there are m kinds of fundamental units whose magnitude may be changed and in terms of which any equation of relationship must be a complete equation. Suppose this system of measurement is being applied to a physical system in which there are n parameters, including all dimensional constants. Then in general, unless there is some special relationship, the n parameters can be combined into only $n-m$ independent dimensionless products, and any possible functional connection is a function of only $n-m$ arguments instead of the full n . If there are special relationships between the exponents in the dimensional formulas of the parameters, the

number of independent dimensionless arguments may be either greater or smaller than $n-m$. It is possible to include these special exceptional cases in a general formulation, but in practice they are usually immediately obvious to inspection, so that we shall avoid here the complication of a perfectly general formulation.

Since products of powers of dimensionless products are themselves dimensionless products, there is no unique way of writing the $n-m$ dimensionless products—it is only the number which is determined. The precise form in which these products are to be written must be chosen with discretion, to suit the purposes of the application.

Making the Dimensional Analysis—The steps in a dimensional analysis of any concrete problem are as follows. We first have to decide what sort of physical system we are dealing with in the sense that we have to decide what is the nature of the fundamental governing equations. For example, it may be a mechanical system governed by the equations of mechanics, or it may be an electromagnetic system governed by the equations of electrodynamics. We then have to decide on the system of measurement, which involves fixing the sort of quantities that are to be treated as primary and setting up the definitions of the secondary quantities. This will involve setting up the dimensional formulas, in cases of doubt it will pay to write out the definitions explicitly. We then imagine the fundamental equations written for this system of measurement, paying especial attention to any dimensional constants that may be used in writing the equations. We then make a list of all the parameters entering the particular problem, including both so-called physical quantities and dimensional constants. We write the dimensional formulas of all these parameters. We next form all the independent dimensionless products of these parameters, this is to be done by a method of solution of simple algebraic equations in the unknown exponents, as will appear from a study of the detailed examples. If necessary, the dimensionless products which first present themselves are to be rearranged so as to be more convenient for the particular problem. An arbitrary function of these dimensionless products is then to be set equal to zero, and this function is to be rearranged to suit the special exigencies. This is as far as dimensional analysis proper can go. An additional step is often taken by further restructuring the form of the function by applying any special information that one may have as, the effect of a certain parameter on the function disappears if the parameter is very small (or very large). Lord Rayleigh was especially successful in supplementing the dimensional analysis proper with other sorts of general physical information.

It is especially to be noticed that no detailed solution of the governing equations is assumed—in fact, if we were in a position to give the detailed solution we could get the complete relationship, and dimensional analysis to that extent would be superfluous. All we need to know about the fundamental equations is what goes into them—in particular, what dimensional constants. It follows that we can apply the method to situations so complicated that it would be hopeless to attempt a detailed writing out of the equations, much less to obtain a solution, and in fact the most important applications of dimensional analysis are precisely to such complicated situations.

It is important to notice that a great deal of flexibility is possible in the form in which the governing equations are written, both in the system of measurement and in the definitions for the secondary quantities. The governing equations do not have to be written in any unique canonical form, but may be specially adapted to the particular problem. This flexibility is to be utilized so as to reduce the number of independent dimensionless products to a minimum. The larger the m , other things being equal the smaller the number of dimensionless products. Special problems often permit an increase in m . For example a problem in mechanics or hydrodynamics will ordinarily be set up with conventional mechanical units, mass, length and time as primary. But if the physical situation is of such a special character that the connection between force, mass and acceleration does not enter, as in a problem of steady motion like the Sir

George Gabriel Stokes problem of the fall of a sphere in a viscous medium where accelerations are zero, then force may be used as an independent primary unit, and the problem may be set up with four independent primary units force, mass, length and time, instead of three. The result is a reduction in the number of dimensionless arguments, and hence more highly specialized information. If one chooses, any problem in mechanics may be set up in these four primary units, but in most problems the equation connecting force, mass and acceleration will be necessary, and this equation, written in four primary quantities, demands a new dimensional constant, the factor of proportionality between force and mass times acceleration. In general, then, the gain in increasing the number of primary quantities is nullified by an increase in the number of dimensional constants, so that the number of independent dimensionless products is unchanged.

It obviously requires experience and insight to know when the special situations arise, dimensional analysis yields an amount of information dependent on the skill and experience of the analyst. Positive errors are never introduced by failure to recognize these special situations—it is only that less than the maximum information is obtained. In the limiting case, where one has nothing whatever to contribute to a knowledge of the nature of the physical system, dimensional analysis does not give incorrect results, but only trivial results.

We have seen that any empirical connection whatever can be thrown into complete form by introducing an appropriate dimensional constant as a factor multiplying each physical parameter. If there are n' physical parameters, in this case there will be $2n'$ dimensional parameters altogether, including the dimensional constants, and hence $2n' - m$ dimensionless products. The result is some undetermined function of $2n' - m$ arguments. But in general $n' > m$, so that $2n' - m > n'$, and we know less by applying the analysis than before, because we knew in the beginning that there was some functional connection between the n' parameters. Although positive errors are not introduced by using an unnecessarily large number of independent quantities, it is obviously fatal to omit from the analysis any parameter which should actually enter the results. Experience and understanding are required of the analyst in order to ensure this. Consider now several typical applications.

(1) *The Simple Pendulum*—This is the conventional introductory problem. The physical parameters defining the simple pendulum may be taken to be the mass of the bob and the length of the suspending rod. The problem is obviously one in mechanics, and we may take as the fundamental units, mass, length and time. A detailed solution of the equations of motion will give the time of any complete oscillation, and this oscillation may be characterized by its angular amplitude. Our physical command of the situation is sufficient to show that the time of oscillation for any particular amplitude must be uniquely determined, since the bob starts from rest at the extreme point of the oscillation and the boundary conditions and the equation of motion determine a unique solution. The equations of motion will involve the force on the bob, and this will involve the acceleration of gravity, that is, in the equations of motion will appear the dimensional constant g . The detailed solution should therefore give a relationship between mass of bob, m , length of pendulum, l , angular amplitude of oscillation, θ , acceleration of gravity, g , and the period of oscillation, τ . This is a complete relationship, being deduced by mathematical manipulations from a complete equation, and therefore the II theorem applies. We write the parameters which enter

Parameter	Dimensional formula
m	M
l	L
θ	\circ
g	LT^{-2}
τ	T

The II theorem instructs us to form all the independent dimensionless products. There will in general be 2, because n , the number of parameters, is here 5, and m , the number of primary units,

is here 3. One of these products, θ , is obvious on inspection. We then must form one dimensionless product from the four remaining parameters. The exponents in the dimensionless product are unknowns which we write as $\alpha, \beta, \gamma, \delta$. We must now find these four quantities so that $m^\alpha l^\beta g^\gamma \tau^\delta$ is dimensionless. Substitute the dimensional formulas for the parameters. $M^\alpha L^\beta (LT^{-2})^\gamma T^\delta$ must be dimensionless, or the total exponents of M, L and T must vanish. This condition gives three algebraic equations

$$\begin{cases} \alpha = 0 \\ \beta + \gamma = 0 \\ -2\gamma + \delta = 0 \end{cases}$$

There are three equations and four unknowns, which means that one unknown may be assumed arbitrarily. Take δ as the arbitrary one. Then the solution is $\alpha = 0, \gamma = \frac{\delta}{2}, \beta = -\frac{\delta}{2}$. The dimensionless product is $l^{-\frac{\delta}{2}} g^{\frac{\delta}{2}} \tau^\delta$. The II theorem states that the solution is some functional relationship between the two independent products, or

$$F[(l^{-\frac{\delta}{2}} g^{\frac{\delta}{2}} \tau^\delta), \theta] = 0,$$

where F is completely undetermined.

This equation may be rearranged by solving for the quantity in parenthesis, giving

$$l^{-\frac{\delta}{2}} g^{\frac{\delta}{2}} \tau^\delta = f(\theta),$$

where f is completely undetermined. This again may be rearranged as

$$\tau = \frac{l}{g} f(\theta)$$

That is, the time of swing is independent of the mass, proportional to the square root of the length, and inversely proportional to the square root of the acceleration of gravity. As far as this analysis goes it may be any function of the amplitude. The detailed solution would show that for small amplitudes f has approximately the constant value 2π .

Even in this simplest of all problems we have had to make approximations and utilize special knowledge. For example, friction has not entered our result, yet every actual pendulum experiences friction, both from the resistance of the air and from imperfect elasticity of the supports. A precise formulation of the equations of motion would have involved the coefficient of viscosity of the air and an internal damping coefficient for the material of the supports. There would have been two more parameters, and the final result would have involved an arbitrary function of three arguments instead of one. Furthermore, we would have lost the information that we now have that time varies as the square root of the length. Suppose, for example, that we consider the effect only of the damping of the air. We would have had one more parameter, the viscosity of air, μ , of dimensions $ML^{-1}T^{-1}$, and one more argument of the function. Our result would have had the form

$$F[(l^{-\frac{\delta}{2}} g^{\frac{\delta}{2}} \tau^\delta), (\mu l^{-\frac{1}{2}} g^{\frac{1}{2}} \mu^{-1}), \theta] = 0$$

In this solution l cannot be isolated, and the dependence on l is tied up with that of the other parameters. Our original simplified analysis can be justified only by the additional knowledge, acquired either by experiment or by other considerations, that the effect of viscosity of the air on the period is vanishingly small. This sort of supplemental information is almost always necessary to make dimensional analysis yield useful results.

(2) *The problem of the resistance experienced by some body of definite shape moving at constant velocity through a body of fluid of dimensions indefinitely large compared with those of the moving body*. Special cases of this problem are the resistance encountered by a projectile, by a submarine in deep water, by an aeroplane, or by a falling raindrop. The case of the ship is not included because for a ship, part of the resistance to motion arises from the creation of surface waves against gravity. The converse problem obviously is covered also, that is, the problem of the force exerted on a stationary obstacle by an infinite mass

(3) *The Problem of Heat Transfer*—A body of given shape is surrounded by an infinite stream of liquid flowing past it at uniform velocity. The body is maintained at a given temperature higher than that of the remote parts of the stream. It is required to find the rate of heat interchange between body and stream. A complete solution of this problem would be excessively complicated, we shall make several essential simplifications. The heat convected away by the stream is known if we know the velocity distribution in the liquid and know the rate of heat transfer into each element of its volume. We assume that the velocity is so low that the flow is non-turbulent, in this region the distribution of flow velocity is independent of the viscosity of the fluid, although the forces are not. Further, the preceding problem shows that in this range the density of the fluid does not affect the velocity distribution. At the surface of separation of liquid and body there is no surface slip. The rate of heat transfer into the liquid at the surface depends on the temperature gradient in the liquid at the surface, and this will depend on the thermal conductivity of the liquid, its thermal capacity, and the rate at which new liquid is brought up by the motion, that is, on the velocity of the liquid. We suppose that the thermal conductivity of the solid body is so much higher than that of the liquid that the thermal conductivity of the solid offers no restriction on the rate of heat transfer from solid to liquid, and therefore the heat conductivity of the solid will not enter.

The conditions in this problem are sufficiently special so that it is advantageous to use a special set of primary units. We have the following table of parameters and dimensions

Name of Quantity	Symbol	Dimensional formula
Rate of heat transfer	h	HT^{-1}
Velocity of fluid	v	LT^{-1}
Temperature difference	τ	τ
Thermal conductivity of liquid	k	$HL^{-1}T^{-1}\tau^{-1}$
Heat capacity of liquid per unit volume	c	$HL^{-1}\tau^{-1}$
Linear dimensions of body	l	L
Shape factors	r_1, r_2	0

Here we use new kinds of fundamental unit, quantity of heat, H , and temperature, τ , while mass does not appear. The justification is in the details, as outlined above. This is a problem in static flow, that is, as far as the velocity of flow is concerned it is a problem in statics and masses do not enter. The equations deal directly with the flow of heat as such, and, since there is no transformation of heat into mechanical work, we are not concerned with the fact that in other kinds of systems heat and mechanical energy are mutually transformable. It is therefore sufficient to treat heat as a primary unit. Furthermore, temperature enters only through temperature differences and through those properties of the body which determine the behaviour when there are temperature gradients. Temperature may, therefore, be treated as a primary unit, in spite of the fact that there are other kinds of physical systems whose behaviour involves the fact that absolute temperature is proportional to kinetic energy per degree of freedom.

Disregarding the shape factors, we have six parameters expressed in terms of four primary units. Unless there is something exceptional in this situation the Π theorem leads us to expect two dimensionless products. Since we are interested in h , we choose one of the products without h . Detailed carrying through of the solution shows that there is nothing exceptional here, and the two independent dimensionless products are found to be $h/kl\tau$ and lvc/k . The solution is

$$F[h/kl\tau, lvc/k, r_1, r_2] = 0,$$

where F is arbitrary. The solution may be rearranged and solved for h , giving

$$h = kl\tau f[lvc/k, r_1, r_2],$$

where f is arbitrary. The rate of heat transfer is therefore pro-

portional to the temperature difference. In a model experiment, identical values of the function f can be kept only by increasing the velocity in proportion as the linear dimension of the body is decreased. In the range in which the transfer is proportional to the velocity, it is also proportional to the square of the linear dimensions, that is, to the area and independent of the thermal conductivity of the liquid. This means that under these conditions the transfer is entirely a convective phenomenon. In this range the effect of increasing the velocity of flow is the same as decreasing the heat capacity by the same factor.

The importance of a judicious choice of units adapted to the particular problem is particularly apparent here. If we had taken temperature to be a secondary quantity, and defined it as proportional to the kinetic energy of the atoms (as we might in perfect consistency with kinetic theory), the dimensional formulas and all the parameters would have been expressed in terms of three instead of four primary units, we would have had one more dimensionless product, the arbitrary function would have involved one more argument, and the relationships that we could have deduced would have been correspondingly less restricted, although not actually incorrect. The point is that the phenomena of kinetic theory do not enter this problem, and we are only handicapping ourselves unnecessarily if we try to bring them in by way of the definitions. A problem in which the connection between temperature and energy has to be brought in by way of the units is, for example, the very simple problem of the pressure volume temperature relation for a perfect gas.

(4) *Electromagnetic Problems*—In dealing with problems in electrodynamics the question of the most suitable system of primary units is likely to prove more troublesome than in mechanical problems, because of the much larger number of alternative systems which have been proposed and which are in actual use. From the point of view of dimensional analysis the only requirement is that the system is consistent and adapted to the particular problem in hand. This requirement does not fix the system of measurement uniquely, and alternative definitions and corresponding alternative sets of dimensional formulas are possible in dealing with most of the problems of electrodynamics. There has been much controversy and misunderstanding in this connection, at one time an engineering society tried to determine the correct point of view by majority vote. The view has been very common that a dimensional formula expresses the essential physical nature of a quantity. From this point of view the present indeterminateness in dimensional formulas is an expression of our present incomplete knowledge of the complete physical mechanism, and the time is anticipated when we shall be able to write the correct dimensional formula for the dielectric constant and the magnetic permeability of empty space. The thesis is often defended that when this occurs all fractional exponents will disappear from all dimensional formulas. This attitude has a partial explanation as a historical survival from the time when the displacement current of Maxwell's equations was thought to indicate a movement of an electrical fluid which pervaded all space and which was everywhere elastically tethered to a second all-pervading rigid framework. This point of view has outlived any usefulness it may ever have had in suggesting experiment, it appears not to be unusual for a point of view to survive in its effect on philosophical attitude after it is dead in its original significance.

As an illustration of the application of dimensional analysis to a problem of electrodynamics, consider the classical problem of the electromagnetic mass of the electron. The electron is conventionalized by specifying its total charge, e , and its equivalent radius, a . To find the electromagnetic mass the electron may be placed in a constant electric field, and the resultant acceleration determined. If this acceleration should prove to be constant, independent of the velocity of the electron, then its behaviour is similar to that of a mechanical particle with ordinary mechanical mass, and it is proper to speak of electromagnetic mass. However, until the solution has been carried through one cannot say whether the electron has an electromagnetic mass or not. In carrying through the solution the field equations of

electrodynamics will be used, and into them will be substituted the parameters characterizing the electron. For the solution of theoretical problems of this nature the Gaussian system of units is often regarded as most convenient, and we shall suppose this to be the system used. In the field equations written in this system one dimensional constant occurs, c , the dimensions of velocity, and numerically equal (by experiment) to the velocity of light. Our problem is then to build up a quantity of the dimensions of mass from the three quantities: electronic charge, e , electronic radius, a , and c . In the Gaussian system e^2 has the dimensions ML^3T^{-2} . Inspection shows that ae^2/c^2 is of the dimensions of mass, so that the point of view which anticipated an electromagnetic mass is to this extent justified and the mass is proportional to ae^2/c^2 . The constant of proportionality can be found only by a detailed solution and will depend on the manner of distribution of the charge.

Applications to Theoretical Physics.—The general scheme of applying dimensional analysis to theoretical physics is not different from that in the applications already considered, provided the underlying mechanisms of the system are sufficiently understood. The method may, however, be applied as a tool of preliminary exploration in situations which are not yet completely understood, in order to find whether certain lines of attack are sufficiently promising to justify more detailed and elaborate development. A well known example is the application by Albert Einstein to a discussion of the infra-red characteristic frequency of solids. Before Einstein, no connection had been envisaged between the mechanism responsible for the ordinary elastic behaviour of a solid and that controlling its optical behaviour. Einstein suspected that the forces resisting the ordinary elastic deformations in a solid were the same in character as those responsible for the characteristic optical frequency in the infra-red. An exact working out of the point of view would obviously have demanded detailed and laborious calculations, which one would not lightly enter upon. A preliminary dimensional analysis was therefore made. A connection is sought between characteristic frequency, ν , compressibility, K , the mass of the atom, m , and the number of atoms per cm^3 , N . The dimensions of these quantities in ordinary mechanical units are respectively T^{-1} , $M^{-1}L^2T^2$, M , and L^{-3} .

There is in general one dimensionless product, and the result s obtained that

$$\bar{K} = \text{numerical const} \times \nu^{-2} N^{-1} m^{-1}$$

A connection of the suspected sort is therefore possible. However, in its present form very little significance can be attached to this result, because in general a dimensionless product may be formed with any four quantities chosen at random. If the exponents in the dimensional formulas of the parameters had provided a special relationship that the dimensionless product was impossible, then the result would have been of immediate significance, but it would have been negative, and the line of enquiry would have been dropped as impossible. However, in the actual situation further argument is required to find whether the existence of this dimensional relation is significant, and this further argument was supplied by Einstein from an examination of the numerical value of the constant of proportionality.

Substituting actual numerical values for the physical parameters of a representative solid, copper,

$$\nu \times 10^{-13} \text{ for } \bar{K}, \quad 7.5 \times 10^{23} \text{ for } \nu,$$

$$7.5 \times 10^{23} \text{ for } N,$$

$$1.06 \times 10^{-25} \text{ for } m,$$

and gives the value 0.18 for the numerical constant, a value neither very large nor very small. Einstein's argument is based on the empirical observation that any very large or very small numbers which appear in equations of physics derived theoretically have their origin in physical parameters, such as the charge on the electron or the number of atoms per cm^3 . On the other hand, numbers which are the result of purely mathematical calculations are likely to be neither very large nor very small.

In the analysis above a number was found, 0.18, neither very large nor very small, so that it might have been the result of mathematical operations on certain fundamental equations containing the physical parameters. The point of view therefore appears to be worth further investigation. It is well known that detailed analysis did justify the general point of view, and the whole modern theory of specific heats at low temperatures has come out of it. The method is admittedly far from rigorous, nor can it be made rigorous, it is intended only to be suggestive, as a tool for preliminary exploration.

Use in Checking Equations.—Another use of dimensional analysis, which often saves much time, is in checking the correctness of a theoretical derivation of a formula. An equation derived from theoretical considerations should in general be a complete equation, the terms should then all have the same dimensions. Simple errors in manipulation are often discoverable by observation of a failure of dimensional homogeneity, and the place of origin of the error may be quickly traced. Consider, for example, a formula in thermodynamics for the adiabatic thermal expansion in terms of the isothermal expansion and other quantities, which might appear as

$$\left(\frac{\partial v}{\partial T}\right)_s = \left(\frac{\partial v}{\partial T}\right)_p + C_p \left(\frac{\partial v}{\partial p}\right)_T / \left(\frac{\partial v}{\partial T}\right)_p$$

We ask whether this expression is dimensionally homogeneous. The dimensions of thermodynamic quantities are often expressed most conveniently in terms of pressure (p), volume (v), and temperature (T) taken as primary. The dimensions of $\left(\frac{\partial v}{\partial T}\right)_s$

in the formula are νT^{-1} , as also are those of $\left(\frac{\partial v}{\partial T}\right)_p$. The dimensions of C_p , defined in this case as the heat required to raise the temperature one degree, are $\nu T^{-1} p^{-1}$, p having the dimensions of heat or energy. Substitution gives ν for the dimensions of

$$C_p \left(\frac{\partial v}{\partial p}\right)_T / \left(\frac{\partial v}{\partial T}\right)_p$$

This differs by T^{-1} from the dimensions of the other terms, so that there must be some error. Consideration would show that a factor T^{-1} had been lost, and the correct formula is

$$\left(\frac{\partial v}{\partial T}\right)_s = \left(\frac{\partial v}{\partial T}\right)_p + C_p \left(\frac{\partial v}{\partial p}\right)_T / T \left(\frac{\partial v}{\partial T}\right)_p$$

Use in Changing Units.—By writing out the dimensional formulas of various quantities a method is afforded of finding how the numerical magnitudes of any concrete examples change when the size of the primary units of measurement change. The method is so simple that no elaborate or formal exposition is necessary, it will be sufficient to give several illustrative examples. The method has already been applied in an earlier discussion in this article.

Suppose that a given body is moving with a velocity of 60 mi per hr and we wish to find what its velocity would be in feet per second. Since 1 mi contains 5,280 ft and 1 hr contains 60 × 60 sec, we may write

$$60 \frac{\text{mile}}{\text{hour}} = 60 \frac{5,280 \text{ ft}}{3,600 \text{ sec}} = 88 \frac{\text{ft}}{\text{sec}}$$

Or, what is the pressure of the atmosphere, which we may take as 15 lb per sq in, expressed in kilograms per square centimetre? One pound is equal to 0.4536 kg, and 1 in equals 2.54

$$\text{cm. Hence, } 15 \frac{\text{lb}}{\text{in}^2} = 15 \frac{0.4536 \text{ kg}}{(2.54 \text{ cm})^2} = 15 \frac{0.1536 \text{ kg}}{(2.54)^2 \text{ cm}^2} = 1.054 \text{ kg/cm}^2$$

The method illustrated is obviously general. In fact it may be extended to much more complicated sorts of examples in which the conversion is between systems of units different in general nature, as from a system with mass, length and time as fundamental to one with force, velocity and energy as fundamental.

In applying the method the symbolic and abbreviated character of the notation is especially not to be lost sight of. We do

not, for example, divide a mile by an hour, but we divide a number obtained by the physical operation for measuring a distance in miles by a number obtained by the physical operations for measuring a time interval in hours. Our question is, what number would we have obtained if we had operated on the same physical system with the operation for measuring a length in feet and the operation for measuring a time in seconds?

Critical Comments—While there is general agreement as to the details of the application of dimensional analysis to any concrete problem, and also with regard to the specific form of the results, there has not by any means been agreement with regard to the philosophy of the subject, and many questions are still controversial. The view presented here is one which apparently is increasingly accepted in the U.S. The crux of this point of view is that dimensional analysis is an analysis of an analysis that is, an analysis of the implications of the fact that methods of analyzing experience have been found profitable which employ certain types of measuring process and certain methods of mathematical treatment of the results of the measurements. There is nothing absolute here, but a great deal of flexibility.

On the other hand, there has been a view, widely held by British authors and also on the continent, that the dimensions of a physical quantity have a much more esoteric significance, that dimensions refer to its essential physical nature, and that the correct dimensions are unique and sometime perhaps may be discovered. Examples of this point of view have been given in the text, this opinion leads, for example, to an intuitive proof of the necessary dimensional homogeneity of all physical equations, and also to an aversion for fractional exponents in dimensional formulas, the occurrence of which is supposed to indicate that certain essential dimensions have been suppressed. Somewhat connected with this point of view is the feeling, held by many contemporary writers, that it is necessary to distinguish two different sorts of operation in our handling of physical situations: that is, ordinary mathematical or arithmetical operations with numbers, and corresponding operations with physical quantities. Thus, according to this view, a velocity is the quotient of a physical length by a physical time.

Contrasted with these points of view, the point of view of this article may be characterized as a minimum point of view. The thesis is whether or not it is possible to give satisfactory meaning to operations with physical quantities, or whether or not there is reason for thinking that things have an ultimate essential physical nature. For present purposes it is not necessary to settle these questions, but everything that we actually need or use in applying dimensional analysis is contained in the considerations set forth in this article. In particular, the various symbols in a dimensional formula perform the function of indicating the different sorts of physical operation that give rise to certain numbers that we use in our calculations. (See PHYSICAL UNITS)

BIBLIOGRAPHY—The bibliography is very extensive, particularly that of applications to model experiments and other problems of engineering. Only a few of the references to more fundamental aspects will be indicated here.

Typical of the view expressed in this article and coming to be accepted at least by U.S. physicists: P. W. Bridgman, *Dimensional Analysis* (1922 and 1931), John C. Oxley, *American Physics Teacher*, 2, 85 (1934), R. T. Burge, *American Physics Teacher*, 3, 102, 171 (1935).

Representing other U.S. points of view: Edgar Buckingham, *Nat* 96, 208 and 396 (1915), *Phil Mag* 42, 696 (1921), *Jour Amer Soc Nav Eng*, 33, 227 (1921), R. C. Tolman, *Phys Rev* 9, 237 (1917), G. N. Lewis, *Phil Mag*, 739 (1925).

handeling op 25 Mei 1935 Aangeboden aan Prof Dr P. Zeeman, 1935 (Grazehagen, 1935) (P. W. B.)

DIMINISHING RETURNS, in economics, represents the special application to land of the more generalized "law of diminishing productivity." This latter law may be stated as follows: "The size of the product obtained in a given productive process varies greatly according to the way in which the various agents of production are combined. If the supply of all other agents is kept constant, while the supply of one specific agent is increased, the average product per unit of this specific agent may increase to a maximum point, but, thereafter will, as a rule, diminish continuously, though often irregularly." This law is applicable to all types of production. Economists early noted the application of this law to land and called it "the law of diminishing returns." They observed that, beyond a certain point, as a greater value of labour and other agents of production are applied to a given area of land, the physical product obtained per additional unit of value invested on the land tends to diminish continually. Experience everywhere confirms the existence of this principle.

Any farmer knows that it is unprofitable to increase the intensity of use or cultivation of land beyond a certain point. It is a generally accepted fact that, when population density in a nation increases beyond an optimum point, average productivity per capita diminishes, and hence poverty increases.

(See ECONOMICS) (W. I. K.)
DIMINUENDO (It.), diminishing, *se*, as used in music (abbr *dim*.), in loudness, otherwise getting softer. *Decrescendo* and the sign — have the same meaning.

DIMINUTION, a term in music applying when a given theme or passage is played in a "diminished" form, *se*, in notes of shorter duration, "augmentation" signifying the converse procedure.

DIMITRIEVIĆ, DRAGUTIN (1876-1917) COLONEL, Serbian soldier and conspirator, was born on Aug. 17, 1876, and was the principal organizer of the conspiracy which ended in the murder (1903) of King Alexander (q.v.) Obrenovich of Serbia and his wife Draga. He was at first treated with great consideration by King Peter Karageorgjević, and advanced rapidly in his profession. He became lecturer in tactics at the Military Academy of Belgrade, and contributed largely to the reorganization of the Serbian army. In time, however, he became estranged from the dynasty, and as the semiofficial "Narodna Obrana" was too lukewarm, in his opinion, he founded (May 1911) the secret society "Ujedinjenje ili Smrt" (Union or Death), a league composed mainly of officers, and known generally as "the Black Hand," which aimed at uniting all southern Slav districts, by no matter what means. This league, and Dimitrijević himself, took an active part in the comitadj warfare in Macedonia, and also in the anti-Austrian propaganda in Bosnia.

In June 1913 Dimitrijević was appointed chief of intelligence of the Serbian general staff. He was the prime author and organizer of the murder of Sarajevo. The "Black Hand" had quarrelled with the civilian administration and Radical party over the latter's administration in Macedonia. On Dec. 15, 1916, Dimitrijević and his principal partisans were arrested at Salonika on a charge of conspiring to deliver the Serb front to the enemy, he was condemned to death for inciting to mutiny and conspiring to assassinate the crown prince (later king) Alexander of Serbia, and shot June 1917.

Dimitrijević (commonly known as "Apis") was a man of great courage, intelligence, patriotism and energy, but ruthless and utterly unscrupulous in his methods. Personal details are given most fully in Boghichevich, *Le Procès de Salomon* (1927), while the evidence regarding the Sarajevo crime is best given in R. W. Seton-Watson, *Sarajevo* (1927).

DIMITY, derived from the Gr. *dimuros* "double thread," through the Ital. *dimuto*, "a kind of course linze wolze" (Floro, 1611), a cloth commonly employed for bed upholstery and curtains, and usually white, though sometimes a pattern is printed on it in colours. It is stout in texture, and woven in raised patterns.

DIMORPHISM, the property of assuming two forms. In crystallography (*qv*), two substances which are identical in chemical composition but different in crystalline form, and consequently in others of their physical properties, are *dimorphous*.

In biology the word is used when there are two distinct varieties of an organism which freely interbreed, thus, in plants, the pin eyed and thrum eyed varieties of primrose (*Primula*) are examples of dimorphism, among animals, some female mimetic butterflies show dimorphism, changing their appearance to resemble a different model (see *MIMICRY*), some birds, *e.g.*, certain owls, also exhibit dimorphism. In addition, many animals exhibit sexual dimorphism (see *SEX*) in which the two sexes are sharply differentiated from one another, *e.g.*, deer, birds of paradise, many butterflies, etc.

DINAJPUR, a town and district of British India, in the Rajshah division of Bengal. The population of the town in 1941 was 28,190. The district has an area of 3,953 sq mi and a pop (1941) of 1,926,833. It is a flat alluvial plain broken in the south by a slightly elevated tract known as the Barind, and in the north-west by low hills, along the banks of the Kulik river. The principal rivers are the Atrai and Jamuna and the Karatoya, which forms the eastern boundary for 50 mi. Rice is the staple agricultural product. The district is partly traversed by the main line of the Eastern Bengal State railway and by the line to Bihar, which takes off at Parbatpur. Pillars and copperplate inscriptions have yielded numerous records of the Pala kings of Bengal. Interesting ruins exist at Devkot and Ghoraghat which were military stations under the early Mohammedan rulers of Bengal.

DINAN, a town of northwestern France, capital of an arrondissement in the department of Côtes du Nord, 37 mi E of St Brieuc on the Ouest-Etat railway. Pop (1936) 11,711. Dinan, a stronghold of the dukes of Brittany was besieged by the English under the duke of Lancaster in 1359, during which siege Du Guesclin and an English knight called Thomas of Canterbury engaged in single combat.

Dinan stands on a height on the left bank of the Rance (here canalized), some 17 mi above St Malo, with which it communicates by means of small steamers. It is united to the village of Lanvallay on the right bank of the river by a granite viaduct 130 ft. in height. The town is almost entirely encircled by the mediaeval ramparts, strengthened with towers and, on the south, a castle of the late 14th century, now a prison. Three old gateways also remain. The church of St Malo is late Gothic, that of St Sauveur, Romanesque and Gothic intermingled. In the latter church a granite monument contains the heart of Bertrand Du Guesclin. The quaint winding streets of Dinan are often bordered by mediaeval houses. It is a tourist centre. Near the town are the ruins of the château and the Benedictine abbey at Léhon, and not far off is the now dismantled château of La Garaye. Dinan is the seat of a subprefect. There is trade in grain, cider, wax, honey, butter and other agricultural products. Leather is manufactured.

DINANT, an ancient town in the province of Namur, Belgium, on the Meuse, with the station and the suburb of St Medard. Pop (1930) 6,943. As early as the 7th century it was a dependency of the bishopric of Tongres. From the 10th century to the French revolution it was a fief of the prince bishopric of Liège. In 1040 a castle was built on a rock dominating the town. In the 13th century, with a population of 60,000, and 8,000 workers in copper, Dinant was one of the most flourishing cities in Walloon Belgium until it incurred the wrath of Charles the Bold. In 1466 Charles, in his father's name, laid siege to Dinant, and carried the place by storm, killing most of the combatants. In 1675 Dinant was taken by Louis XIV, and remained in French hands for nearly 30 years. The citadel on the cliff, 300 ft or 408 steps above the town, was fortified by the Dutch in 1818, but was dismantled later. Half way up the cliff is the grotto of Montfat, 13th century.

The church of Notre Dame (13th century) stood immediately under the citadel, flanking the bridge, and was a remarkably complete illustration of Gothic architecture with a curious slate-covered spire shaped like a long pumpkin.

Dinant was practically destroyed in August 1914 during the German invasion, and 670 of its inhabitants were shot, but after 1918 it was largely restored. It again suffered heavily in the May 1940 campaign.

Dinant is a summer resort and also a convenient central point for excursions into the Ardennes.

DINAPORE, a subdivisional town and cantonment of British India, in the Patna district of Bihar, on the right bank of the Ganges. Pop (1941) 40,057. In 1857 the sepoy regiments here who had been allowed to retain their arms broke into open mutiny when an attempt was made to disarm them. The majority crossed over the Son into Shahabad where they joined the rebels under Kuar Singh and laid siege to Arrah.

DINAR The monetary unit of Serbia, and since World War I, of Yugoslavia, divided into 100 paras. At par, the dinar is equivalent to 2982 cents in the currency of the United States.

Gold coins are of 20 and 10 dinars in denomination, and silver is coined into pieces of 5, 2, 1 and $\frac{1}{2}$ dinars, respectively. Nickel coins circulate, in the form of 20, 10 and 5 paras, while bronze is struck into coins of 2 paras. With the dinar equivalent to 176 cents or about three farthings, 2 paras would be only 1/100th of a penny.

National bank notes circulate in Yugoslavia. In 1920, 3,344,000,000 dinars were outstanding, and by 1924 the volume had risen to 6,000,000,000. Concurrently, the dollar exchange fell from 295 to 149 cents.

The world depression of the 1930s and the outbreak of World War II in 1939 caused further violent fluctuations in the exchange value of this and other currencies.

(See also CURRENCY)

DINARD, a seaside town of northwestern France in the department of Ille-et-Vilaine. Pop (1936) 6,541. The town, the chief watering place of Brittany, stands on a rocky promontory at the mouth of the Rance opposite St Malo, which is about 1 mi distant. It is a favourite resort of English and Americans, as well as of the French, its attractions being the beauty of its situation, the mildness of the climate and the good bathing. It has two casinos and numerous luxurious hotels and elegant villas. The adjoining watering places of St Enogat, St Lunaire and St Brac are increasing in importance.

DINDIGUL, a town of British India, in the Madura district of Madras, 880 ft above the sea, 40 mi from Madura by rail. Pop (1941) 56,275. Dindigul is a trade centre, and has a considerable manufacture of tobacco, a large cotton ginning and pressing factory, and tanneries. The town has manufactures of cloth and safe locks and an export trade in cotton, coffee, grain and cardamoms. Approximately one ninth of the population is Christian. There is an industrial school. The ancient fort, well preserved, stands 350 ft above the town, this was formerly a position of great strategic importance, commanding passes into Madura from Combaratore, and figured prominently in the military operations of the Mahrattas in the 17th and 18th centuries, and of Hyder Ali in 1755 and the years which followed. After being twice captured by the British it was eventually ceded to the East India Company.

DINDORE, KARL WILHELM (1802-1883), German classical scholar, was born at Leipzig. After completing F. Invernizzi's edition of Aristophanes (1826), and editing several grammarians and rhetoricians, he was, in 1828, appointed extra ordinary professor at Leipzig, a post which he resigned in 1833. He edited Athenæus (1837) and the Greek dramatists, both separately and combined in his *Poetae scenici Graeci* (1830 and later editions). He also wrote a work on the metres of the Greek dramatic poets, and compiled special lexicons to Aeschylus and Sophocles. He edited Procopius for Niebuhr's *Corpus* of the Byzantine writers, and between 1846 and 1851 brought out at Oxford an important edition of Demosthenes, he also edited Lucian and Josephus for the Didot classics. His last important editorial labour was his *Eusebius of Caesarea* (1867-71). Much of his attention was occupied by the republication of Stephanus's *Thesaurus* (Paris, 1831-65), chiefly executed by him and his brother Ludwig, a work of prodigious labour and utility.

of the day or in the evening. The word "dine" comes through Fr from Med Lat *disnare*, for *disjungere*, to break one's fast (*jejunum*), it is, therefore, the same word as Fr *déjeuner*, to breakfast, in modern France, to take the midday meal, *dîner* being used for the later repast.

DINOFLAGELLATA, small celled organisms (class Flagellata), with plant like metabolism, which are present as part of the floating fauna (plankton) of pools, lakes and the sea. They form a certain part of the food supply of other animals (e.g., of fish larvae). (See PROTOZOA.)

DINORNITHIDAE, See MOA

DINOSAURIA, the dominant land animals of the Mesozoic era, they form two orders of reptiles related to the crocodilians and the ancestors of the birds. Although certain of the earlier or more primitive forms were of small size, the dinosaurs as a whole tended to be of gigantic proportions, some members of the group were the largest animals that ever walked the earth. A fair number of dinosaurs were flesh-eaters, but a majority abandoned this mode of life for an herbivorous diet. The primitive dinosaurs were bipeds, and various types remained bipedal throughout the history of the group, in both orders, however, many herbivorous forms reverted to a four footed gait.

The two dinosaur orders are termed the Saurischia and the Ornithischia, the names referring to the fact that in the first order the structure of the characteristic hip bones was fairly comparable to that of other reptiles, whereas in the second order these elements were more bird-like. The oldest saurischians were common reptiles of the late Triassic, most were small, lightly-built, carnivorous bipeds of which *Podokesaurus* (fig. 6) is typical. Some of the saurischians remained relatively small throughout the Mesozoic. *Ornitholestes* of the Jurassic (fig. 1) probably weighed little more than a turkey, and a European contemporary, *Compsognathus*, was no larger than a chicken. In the Cretaceous *Tyrannosaurus*, although as large as an ostrich, was a flesh-eating biped and presently primitive descendant of the other forms.

From such primitive saurischians arose the great flesh-eating bipeds. By the end of the Triassic there were already 100 or 150 of considerable size, and in the Jurassic, *Tyrannosaurus* (fig. 2) is representative of a group of predators, able to cope with any animal of its day. Still larger carnivores evolved in the Cretaceous. *Tyrannosaurus* (fig. 3) stood nearly 20 ft high in hindlimbs, the hind legs are massively built in contrast with the tiny useless "arms." The skull, 4 ft in length, was armed with daggerlike teeth 6 in or more in length.

These bipedal carnivores are generally considered to constitute a suborder Theropoda of the saurischians. In strong contrast to them are the members of the suborder Sauropoda, the amphibious dinosaurs, which reached their peak in the late Jurassic. Some large late Triassic sauropods tended to change from flesh eating to plant feeding. In the Jurassic their descendants had reverted to a four-footed life and appear to have spent much of their time as inhabitants of lagoonal areas rich in soft vegetation. *Brontosaurus* (fig. 7), the "thunder lizard," is a characteristic sauropod. Reaching a length of 67 ft in one mounted specimen this animal is estimated to have weighed perhaps 35 tons. The small head bore but a few simple peg teeth, the food material must have been a very soft type of vegetation. The limbs are massively built in elephantlike columnar fashion, a construction necessary for an animal of such great weight. Even so, it seems doubtful if sauropods could have emerged onto land to any extent, they presumably spent most of their lives in the lagoons, buoyed up by the water.

Diplodocus (fig. 11), originals or replicas of which are found in many museums, was longer (a mounted skeleton measures 87½ ft) but more slenderly built, and weighed perhaps 25 tons. The true giant of the group was *Brachiosaurus* (fig. 4), known both from North America and East Africa. In this form, estimated to have weighed as much as 50 tons, the tail was short but the body massive. The front legs were longer than the hind, in contrast to typical dinosaur build, and the neck was long. In consequence the head was high enough to have seen over a three-story building, *Brachiosaurus* could have lived in relatively

deep bodies of water.

The second of the dinosaur orders is that of the Ornithischia, easily recognized osteologically by the bird like, four-pronged structure of the pelvic bones. Unlike the saurischians, these dinosaurs were, from the first, plant eaters. There were usually numerous leaf-shaped teeth in the back of the jaws for the treatment of vegetable food, but teeth were almost always absent from the front of the mouth, where a horny bill or beak was present.

The ornithischians were slower to develop than their reptile-like cousins, for they are practically unknown in the Triassic. The primitive bird like forms constituted the suborder Ornithopoda. These were bipeds, of which the more primitive genera, such as *Comptosaurus* (fig. 8), were relatively small and lightly built. The front legs were never as strongly reduced in size as in the case of the bipedal saurischians, and it is probable that a four-footed gait was retained to some extent. *Iguanodon* (fig. 10) was a larger and more heavily built genus from the Lower Cretaceous of Europe, the thumb was developed as a spike-like defensive weapon. Best known of ornithopods were the duck-billed dinosaurs of the late Cretaceous, such as *Anatosaurs* [*Trachodon*] (fig. 9). These were amphibious reptiles with webbed feet (impressions have been found of the skin of "mummified" individuals). In many duckbills the bones surrounding the nose expanded into a curious crest or "horn" above the head, this contained the air passage from the nostrils and may have developed in connection with the water-dwelling habits of the group.

As among the saurischians, so in the ornithischians we find a strong tendency for increase in size to be accompanied by a reversion to a four-footed gait. In correlation with the need for protection against contemporary carnivorous dinosaurs, we find that these quadrupeds universally developed defensive structures of some sort. Three subordinal groups may be distinguished. The Stegosauria are the characteristic armoured dinosaurs of the Jurassic, *Stegosaurus* (fig. 12) of North America is the best known of the group, there were related genera in Europe and Africa. The head was small, the short front legs, contrasted with the long hind limbs, are indicative of the earlier bipedal stage in the animal's ancestry. The flanks of the animal appear to have been unprotected, and the armour consisted merely of two rows of large bony plates extending upward from the back, and paired spines borne on the tail. In *Stegosaurus*, as in certain other dinosaurs, the spinal cord shows an enlargement in the hip region, larger than the brain. This indicates a high development of local reflexes for the movement of the hind legs. It will be noted that in large dinosaurs it would have taken an appreciable amount of time for a nerve impulse to travel up the trunk to the brain and back, with consequent problems in the attainment of accurate muscular coordination.

In the Cretaceous dinosaur beds the stegosaurs are replaced by the Ankylosauria. *Ankylosaurus*, *Palaeosincus*, and their allies were armoured forms of a very different sort, sometimes termed "reptilian tanks." The body was low, broad and flattened. The trunk was completely covered above by an armour of larger and smaller bony plates which formed a carapace somewhat comparable to that of a turtle. The limbs were defended by spines projecting outward from the body armour. The broad head and short neck were protected by bone above, and the short tail was sheathed in armour and sometimes furnished with spikes at its tip. The ankylosaurs are not stegosaur descendants but evolved independently from bipedal ancestors.

A third group is that of the Ceratopora, the horned dinosaurs of the late Cretaceous, mainly found in North America. The large head remained in a powerful cutting head. Typical genera developed massive bony horns, a median one above the nose and paired horns somewhat comparable to those of cattle, over the orbits. In *Triceratops* (fig. 5) the nasal horn was small, the paired horns large, in *Monoclonius* the reverse was the case, the nasal horn being the prominent one. Back of the skull region proper, the skull roof is extended into a great frill of bone protecting the neck region—a favourite place for the attack of carnivores. The body stockily built and four-footed carried no armour, although presumably there was a tough hide.

demanding the withdrawal of the French from English territory As the French refused to comply, Dinwiddie in the spring of 1754 sent Washington with an armed force toward the forks of the Ohio river "to prevent the intentions of the French in settling those lands" In May Washington encountered a French force at Great Meadows, in what is now southwestern Pennsylvania, and a skirmish followed which precipitated the French and Indian War Dinwiddie's appeals to the home government, however, resulted in the sending of General Edward Braddock to Virginia with two regiments of regular troops, and at Braddock's call Dinwiddie and other colonial governors met at Alexandria, Va., in April 1755, and planned the initial operations of the war Dinwiddie's administration was marked by a constant wrangle with the assembly over money matters, and its obstinate resistance to military appropriations caused him in 1754 and 1755 to urge the home government to secure an act of parliament compelling the colonies to raise money for their protection In Jan 1758 he left Virginia and lived in England until his death at Clifton, Bristol, July 27, 1770

The Official Records of Robert Dinwiddie, Lieutenant-Governor of Virginia (1751-58), published in two volumes, at Richmond, Va., in 1883-84, by the Virginia Historical Society, and edit by R A Brock, are of great value for the political history of the colonies in this period

DIO CASSIUS (more correctly **CASSIUS DIO**) **COCCEIANUS** (c AD 150-235), Roman historian, born at Nicaea in Bithynia His father was Cassius Apronianus, governor of Dalmatia and Cilicia under Marcus Aurelius, and on his mother's side he was the grandson of Dio Chrysostom After his father's death Dio Cassius went to Rome (180) and became a member of the senate During the reign of Commodus, Dio practised as an advocate and held the offices of aedile and quaestor He was raised to the praetorship by Pertinax (193) but did not assume office till the reign of Septimius Severus, with whom he was for a long time on intimate terms By Macrinus he was entrusted with the administration of Pergamum and Smyrna, and on his return to Rome he was made consul (c 220) After this he obtained the proconsulship of Africa, and again on his return was sent as legate successively to Dalmatia and Pannonia He was granted a second consulship by Alexander Severus, in 229, but soon afterwards retired to Nicaea, where he died Before writing his history of Rome (*Romanika*), Dio Cassius had dedicated to Severus an account of various prodigies which had presaged his elevation to the throne (perhaps the *Ἐξέδρα* attributed to Dio by Suidas), and had also written a biography of his fellow countryman Arrian The history of Rome, which is written in Greek, consisted of 80 books, beginning with the landing of Aeneas in Italy and ending with the reign of Alexander Severus (222-235) We possess books 36-60 (68

circumscription in which administration was exercised The word is equivalent to "assize-districts" But in the reorganization of the empire, begun by Diocletian and completed by Constantine, the word "diocese" acquired a more important meaning, the empire being divided into twelve dioceses, of which the largest—Oriens—embraced sixteen provinces, and the smallest—Britain—four (see *Rome Ancient History*, pp 187, 194-196, which gives a list of the dioceses and their subdivisions) The organization of the Christian church in the Roman empire following very closely the lines of the civil administration (see *CHURCH HISTORY*), the word diocese, in its ecclesiastical sense, was at first applied to the sphere of jurisdiction, not of a bishop, but of a metropolitan For exceptions see Hinschius ii p 39, note 1 The word, however, survived in its general sense of "office" or "administration," and it was even used during the middle ages for "parish" (see *Du Cange, Glossarium*, s "Diocesis" 2)

The practice, under the Roman empire, of making the areas of ecclesiastical administration very exactly coincide with those of the civil administration, was continued in the organization of the church beyond the borders of the empire, and many dioceses to this day preserve the limits of long vanished political divisions The process is well illustrated in the case of English bishoprics But this practice was based on convenience, not principle, and the limits of the dioceses, once fixed, did not usually change with the changing political boundaries Thus Hincmar, archbishop of Reims, complains that not only his metropolitanate (*diocesis*) but his bishopric (*parochia*) is divided between two realms under two kings, and this inconvenient overlapping of jurisdictions remained, in fact, very common in Europe until the readjustments of national boundaries by the territorial settlements of the 19th century In principle, however, the subdivision of a diocese, in the event of the work becoming too heavy for one bishop, was very early admitted, e g., by the first council at Lugo in Spain (559), which erected Lugo into a metropolitanate, the consequent division of diocese being confirmed by the king of the second council, held in 572 Another reason for dividing a diocese, and establishing a new see, has been recognized by the church as duly existing "if the sovereign should think fit to endow some principal village or town with the rank and privileges of a city" (Bingham, lib xvi c 5) But there are canons for the punishment of such as might induce the sovereign so to erect any town into a city, solely with the view of becoming bishop thereof Nor could any diocese be divided without the consent of the primate

In England an act of parliament is necessary for the creation of new dioceses In the reign of Henry VIII six new dioceses were thus created (under an act of 1539), but from that time onward until the 19th century they remained practically unchanged

By the ancient custom of the church the bishop takes his title, not from his diocese, but from his see, i e., the place where his cathedral is established Thus the old episcopal titles are all derived from cities

See Hinschius, *Kirchenrecht*, ii 38, etc.; Joseph Bingham, *Origines ecclesiasticae*, 9 vols (1840); *Du Cange, Glossarium*, s "Diocesis"; *New English Dictionary* (Oxford, 1897), s "Diocese"

DIO CHRYSOSTOM (the "golden mouthed"), (c AD 40-115), Greek sophist and rhetorician, was born at Prusa (mod Bursa), a town at the foot of Mount Olympus in Bithynia Although he did much to promote the welfare of his native place, he became so unpopular there that he migrated to Rome, but, having incurred the suspicion of Domitian, he was banished from Italy He wandered about in Thrace, Mysia, Scythia and the land of the Getae He returned to Rome on the accession of Nerva, with whom and his successor Trajan he was on intimate terms During this period he paid a visit to Prusa, but, disgusted at his reception, he went back to Rome The place and date of his death are unknown, it is certain, however, that he was alive in 112, when the younger Pliny was governor of Bithynia

Eighty orations have come down to us under his name, the *Cornithaca*, however, is generally regarded as spurious, and is probably the work of Favorinus of Arelate Of the extant ora-

DIOCESE

1. A district or territory, especially one of the divisions of the Roman Empire, which was subject to the jurisdiction of a bishop or metropolitan.

tions the following are the most important *Borysthenica* (xxvii), on the advantages of monarchy, addressed to the people of Olbia, and containing information about the Greek colonies on the Black sea, *Olympica* (xi), in which Phedias is represented as setting forth the principles which he had followed in his statue of Zeus, one passage being supposed by some to have suggested Lessing's *Laocoon*, *Rhodiaca* (xxv), an attack on the Rhodians for altering the names on their statues to those of famous men of the day, *De regno* (i iv) addressed to Trajan and describing the stoic ideal kingship, *De Aschylo et Sophocle et Euripide* (li), a comparison of the treatment of the story of Philoctetes by the three tragedians, and *Philoctetes* (lix), a summary of the prologue to the lost play by Euripides. In his later life, Dio, who had originally attacked the philosophers, himself became a convert to Stoicism. To this period belong the essays on moral subjects, such as the denunciation of various cities (Tarsus, Alexandria) for their immorality. Most pleasing of all is the *Euboeica* (vi), a description of the simple life of the herdsmen and huntsmen of Euboea. Amongst his lost works were attacks on philosophers and Domitian, and *Getica*, an account of the manners and customs of the Getae.

BIBLIOGRAPHY—J J Reiske (Leipzig, 1784), A. Emperius (Brunswick, 1844), L. Dindorf (Leipzig, 1857, adds nothing fresh), H. von Arnim (1893-96) G. de Budé (1916). The ancient authorities for his life are Philostratus, *Vit.*, *Soph.* i 7, Photius, *Bibliotheca* cod. 209, Suidas, s.v. *Synesius*, *Alas*. Christ, *Geschichte der griechischen Literatur* (1898), § 520, J. E. Sandys, *History of Classical Scholarship* (2nd ed. 1906), W. Schmid in Pauly *Wissowa's Realencyklopädie*, v. pt. 1 (1905), L. François, *Dion Chrysostome* (1922) (edition with French translation of *De regno* IV, and *Palula Lybica*, with a discussion of the mss and editions). The *Euboeica* has been abridged by J. P. Mahaffy in *The Greek World under Roman Sway* (1890), and there is a translation of *Select Essays* by Gilbert Wakefield (1800).

DIOCLETIAN (GAIVS AURELIVS VALERIVS DIOCLETIANVS) (AD 245-313), Roman emperor 284-305, is said to have been born at Dioclea, near Salona, in Dalmatia. His original name was Diocles. Of humble origin, he held important military commands under the emperors Probus and Aurelian, and accompanied Carus to the Persian War. After the death of Numerianus he was chosen emperor by the troops at Chalcedon, on Sept. 17, 284, and slew with his own hands Arrius Aper, the praefect of the praetorians. Having been installed at Nicomedia, he received general acknowledgment after the murder of Carinus. In consequence of the rising of the Bagaudae in Gaul, and the threatening attitude of the German peoples on the Rhine, he appointed Maximian Augustus in 286, and, in view of further dangers and disturbances in the empire, proclaimed Constantine Chlorus and Galerius Caesars in 293. Each of the four rulers was placed at a separate capital—Nicomedia, Mediolanum (Milan), Augusta Trevirorum (Trier), Sirmium. This amounted to an entirely new organization of the empire, on a plan commensurate with the work of government which it now had to carry on. Diocletian abdicated his sovereignty on May 1, 305, and retired to Salona, where he died eight years afterwards (others give 316 as the year of his death). The end of his reign was memorable for the persecution of the Christians. He hoped to strengthen the empire by reviving the old religion, and the church as an independent State appeared to be a standing menace to his authority. Under Diocletian the senate became a political nonentity, the last traces of republican institutions disappeared, and were replaced by an absolute monarchy. He wore the royal diadem, assumed the title of lord, and introduced the whole ceremonial of Eastern monarchy. His first work was the reform of the administration of the empire, this is partly dealt with under Rome. *Ancient History*, and a brief summary is all that can be attempted here. The titular supremacy of Italy disappears, and a uniform system of administration comes into play throughout the empire. Beginning with Diocletian, local autonomy gradually disappears, and the empire is administered by a huge bureaucracy, entirely dependent on the emperor. The empire was sick of civil war and continual insecurity, and Diocletian and his successors saved it at the price of practically destroying its economic and political life. The old,

regular, intricate system of taxation was abolished, and a simplified, but oppressive and inelastic system substituted, which was really a systematization of the practice of exacting forced contributions of produce and labour, based on acreage, which resulted in the country people becoming compulsorily tied to their land. The responsibility for the city taxes was put on the members of the municipal councils. In the military sphere Diocletian only laid the foundations of the new system, which was the work of Constantine, but he took the first steps by largely increasing the numbers of the army. His attempted stabilization of prices (see DIOCLETIAN, EDICT OF) was a failure. In addition, he adorned the city with numerous buildings, such as the thermae, of which extensive remains are still standing (see Aurelius Victor, *de Caesaribus* 39, Eutropius iv 13, Zonaras xii, 31). The problem before Diocletian was much the same as that before Augustus but the conditions were much more unfavourable. "By his genius Augustus succeeded in restoring not only the State but also the prosperity of the people. Diocletian and Constantine sacrificed the interests of the people to the preservation of the State."

See M. Rostovtzev, *Social and Economic History of the Roman Empire* (1926), and Rome, *History*.

DIOCLETIAN, EDICT OF, an imperial edict (AD 301) fixing a maximum price for provisions and other articles, and a maximum rate of wages. Incomplete copies of it have been discovered, the first (in Greek and Latin) in 1709, at Stratonicea in Caria, containing the preamble and the beginning of the tables down to No. 403. A second fragment (now in the museum at Aix, in Provence) was brought from Egypt in 1809, it adds the titles of the emperors and Caesars, and the number of times they had held them, whereby the date can be determined. Other fragments have been found, e.g., at Elatea, Plataea, and Megalopolis. Latin being the official language all over the empire, there was no official Greek translation. All the fragments come from the provinces which were under the jurisdiction of Diocletian, i.e., the eastern portion of the empire. No traces have been found in the western empire. The articles mentioned in the edict, giving their relative values at the time, include cereals, wine, oil, meat, vegetables, fruits, skins, leather, furs, foot-gear, timber, carpets, and articles of dress, and the wages range from those of the ordinary labourer to those of the professional advocate. The unit of money was a copper coin introduced by Diocletian, of which the value has been fixed at one-fifth of a penny. The punishment for exceeding the prices fixed was death or deportation. The edict was a well-intended but abortive attempt to meet the distress caused by several bad harvests and commercial speculation. The actual effect was disastrous, and the edict soon fell into abeyance.

See *Corpus Inscriptionum Latinarum*, Lactantius, *De mortibus persecutorum*, a contemporary who, as a Christian, writes with natural bias against Diocletian; J. E. Sandys, *Companion to Latin Studies* (1921), with useful bibliography. There is an edition of the whole edict by Mommsen, with notes by H. Blummer (1893).

DIODATI, GIOVANNI (1576-1649), Swiss Calvinist, was born in Geneva on June 6, 1576, of a refugee Protestant family from Lucca. In 1606 he became professor of theology, in 1608 pastor at Diodati, and in 1609 succeeded Beza as professor of theology. Diodati is chiefly famous for his Italian translation of the Bible (1603, edited with notes, 1607). He died at Geneva on Oct. 3, 1649.

Among his other works are his *Annotaciones in Biblia* (1609, Eng. trans. 1648) and polemical treatises, such as *De scilicet Pontificiorum Purgatorio* (1619), *De iusta secessione Reformationis ab Ecclesia Romana* (1628), *De Antichristo*, etc. He also published a French translation of his friend Sarpi's *History of the Council of Trent*.

DIODE, in radio, a type of vacuum tube containing two electrodes, which passes current wholly or predominantly in one direction, and which, therefore, may be used as a rectifier.

DIODORUS CRONUS (4th century B.C.), Greek philosopher of the Megarian school. Practically nothing is known of his life. Diogenes Laertius (ii 111) tells a story that, while staying at the court of Ptolemy Soter, Diodorus was asked to solve a dialectical subtlety by Stilpo. Not being able to answer on the spur of the moment, he was nicknamed *ὁ Κρόνος* (Father Time) by Ptolemy. The story goes that he died of shame at his failure. Strabo, however, says (xv 658, xvii 838) that he took the name of

from Apollonius, his master. He belonged to the Megarian school. His was the famous sophism known as the *Korvion*. The impossible cannot result from the possible, a past event cannot become other than it is, but if an event, at a given moment, had been possible, from this possible would result something impossible, therefore the original event was impossible. From his great dialectical skill he earned the title *δ διαλεκτικός* or *διαλεκτιστάτας*.

See Cicero *De Fato*, 6, 7, 9, Aristotle *Metaphysics*, § 3, Sext. Empiricus *adv. Math.* x 85, Ritter and Preller *Hist. philos. Gr. et Rom.* chap. v §§ 234-236 (ed. 1869).

DIODORUS SICULUS, Greek historian, born at Agrigum in Sicily, lived in the times of Julius Caesar and Augustus. From his own statements we learn that he travelled in Egypt between 60-57 B.C. and that he spent several years in Rome. The latest event mentioned by him belongs to the year 21 B.C. His history, *Bibliotheca historica*, "Historical Library" consisted of forty books, and was divided into three parts. The first treats of the mythic history of the non-Hellenic, and afterwards of the Hellenic tribes, to the destruction of Troy, the second section ends with Alexander's death, and the third continues the history as far as the beginning of Caesar's Gallic War. Of this extensive work there are still extant only the first five books, treating of the mythic history of the Egyptians, Assyrians, Ethiopians and Greeks, and also the 11th to the 20th books inclusive, beginning with the second Persian War, and ending with the history of the successors of Alexander, previous to the partition of the Macedonian empire (302). The rest exists only in fragments preserved in Photius and the excerpts of Constantine Porphyrogenitus. The faults of Diodorus arise partly from the nature of the undertaking, and the annalistic form which he adopts. He lacks the critical faculty, he repeats and contradicts himself, and his simple diction, intermediate between pure Attic and the colloquial Greek of his time, enables us to detect the undigested fragments of the materials which he employed. Yet the *Bibliotheca* is of considerable value as supplying to some extent the loss of the works of older authors, from which it is compiled. Unfortunately, Diodorus does not always quote his authorities, but his general sources of information were in history and chronology, Castor, Ephorus and Apollodorus, in geography, Agatharchides and Artemidorus. In special sections he followed special authorities, e.g., in the history of Sicily, Philistus and Timaeus.

Editio princeps, by H. Stephanus (1559), of other editions the best are P. Wesseling (1746) not yet superseded, L. Dindorf (1828-31), (text) L. Dindorf (1866-68) (revised by F. Vogel, 1883-93 and C. T. Fischer, 1905-06). The standard works on the sources of Diodorus are C. G. Heyne, *De fontibus et auctoritatibus historiarum Diodori*, printed in Dindorf's edition, and C. A. Volquardsen, *Die Quellen der griechischen und lateinischen Geschichten des Diodor* (1868), A. von Meiss, *Rheinisches Museum* (1906), see also L. O. Bröcker, *Untersuchungen über Diodor* (1879), short, but containing much information, O. Maass, *Kleinarch und Diodor* (1894 etc.), G. J. Schneider, *De Diodori fontibus*, 1-iv (1880), C. Wachsmuth, *Einselne in das Studium der alten Geschichte* (1895), *GREEK Ancient History*, "Authorities."

DIODOTUS, Seleucid satrap of Bactria, who rebelled against Antiochus II. (about 255) and became the founder of the Graeco-Bactrian kingdom (Trogus *Prolog.* 41, Justin *xli.* 4, 5, where he is wrongly called Theodotus, Strabo *xi.* 515). His power seems to have extended over the neighbouring provinces Arsaces, the chieftain of the nomadic (Danan) tribe of the Parni, fled before him into Parthia and here became the founder of the Parthian kingdom (Strabo *lc.*). When Seleucus II. in 230 attempted to subjugate the rebels in the east he seems to have united with him against the Parthians (Justin *xli.* 4, 6). Soon afterwards he died and was succeeded by his son Diodotus II., who concluded a peace with the Parthians (Justin *lc.*). Diodotus II. was killed by another usurper, Euthydemus (Polyb. *xi.* 34, 2). Of Diodotus I. we possess gold and silver coins, which imitate the coins of Antiochus II., on these he sometimes calls himself "sovereign," "the saviour." As the power of the Seleucids was weak and continually attacked by Ptolemy II., the eastern provinces and then Greek cities were exposed to the invasion of the nomadic barbarians

and threatened with destruction (Polyb. *xi.* 34, 5), thus the erection of an independent kingdom may have been a necessity and indeed an advantage to the Greeks, and this epithet well deserved. Diodotus Soter appears also on coins struck in his memory by the later Graeco-Bactrian kings Agathocles and Antimachus. Cf. A. V. Sallet *Die Nachfolger Alexanders d. Gr. in Baktrien und Indien*, Percy Gardner *Catal. of the Coins of the Greek and Scythian Kings of Bactria and India* (Brit. Mus.), see also BACTRIA (Ed. M.).

DIOGENES, "the Cynic," Greek philosopher, was born at Sinope about 412 B.C., and died in 323 at Corinth, according to Diogenes Laertius, on the day on which Alexander the Great died at Babylon. When his father was exiled Diogenes was included in the charge and went to Athens. Attracted by the ascetic teaching of Antisthenes, he became his pupil, and rapidly excelled his master both in reputation and in the austerity of his life. The stories which are told of him are probably true, in any case, they serve to illustrate the logical consistency of his character. He injured himself to the vicissitudes of weather by living in a tub belonging to the temple of Cybele. The single wooden bowl he possessed he destroyed on seeing a peasant boy drink from the hollow of his hands. On a voyage to Aegina he was captured by pirates and sold as a slave in Crete to a Corinthian named Xenias. Being asked his trade, he replied that he knew no trade but that of governing men, and that he wished to be sold to a man who needed a master. As tutor to the two sons of Xenias, he lived in Corinth for the rest of his life, which he devoted entirely to preaching the doctrines of self control. It was, probably, at the Isthmian games, during which he used to lecture, that he craved from Alexander the single boon that he would not stand between him and the sun, to which Alexander replied "If I were not Alexander, I would be Diogenes." On his death the Corinthians erected to his memory a pillar on which there rested a dog of Parian marble. His ethical teaching will be found in the article CYNICS (q.v.). It may suffice to say here that virtue, for him, consisted in the avoidance of all physical pleasure, that pain and hunger were positively helpful in the pursuit of goodness, that morality implies a return to nature and simplicity. Both in ancient and in modern times, his personality has appealed strongly to sculptors and to painters. Ancient busts exist in the museums of the Vatican, the Louvre and the Capitol. The interview between Diogenes and Alexander is represented in an ancient marble bas-relief found in the Villa Albani.

The chief ancient authority for his life is Diogenes Laertius vi 20, see also Mayor's notes on Juvenal, *Satires*, xiv 308-314, *Quellen-Untersuchungen zu Leben u. Philosophie des Diogenes von Sinope* (Philolojia, Supplementband 18, 1926).

DIOGENES APOLLONIATES (c. 460 B.C.), Greek natural philosopher, was a native of Apollonia in Crete. Although of Dorian stock, he wrote in the Ionic dialect, like all the *physiologoi* (physical philosophers). He moved to Athens, where his opinions once endangered his life. It is his theories that are ridiculed as those of Socrates in the *Clouds* (264 ff.). An eclectic in doctrine, he drew his views from many sources but his main position is a reconciliation of the theories of Anaximenes and Anaxagoras, which he achieved by taking Anaximenes' theory that air is the one source of being and attributing intelligence to it as well. His most important work was *Περὶ φύσεως* (*De natura*), of which considerable fragments are extant (chiefly in Simplicius); it is possible that he wrote also *Against the Sophists* and *On the Nature of Man*, to which the well-known fragment about the veins would belong, possibly these discussions were subdivisions of his great work.

Fragment in F. Mullach, *Fragmenta philosophorum Graecorum*, 1 (1860), F. Panzerbieter, *Diogenes Apolloniates* (1830), with philosophical dissertation, J. Burnet, *Early Greek Philosophy* (1892), H. Ritter and L. Preller, *Historia Philosophiae* (4th ed., 1869), §§ 59-68, E. Krause, *Diogenes von Apollonia* (1909).

DIOGENES LAERTIUS (or LAERTIUS DIOGENES), the biographer of the Greek philosophers, is supposed by some to have received his surname from the town of Laerte in Cilicia, and by others from the Roman family of the Laerti. Of the circum-

stances of his life we know nothing. It is probable that he flourished during the reign of Alexander Severus (A.D. 222-235) and his successors. His own opinions are equally uncertain. By some he was regarded as a Christian, but it seems more probable that he was an Epicurean. The work by which he is known deals with the lives and sayings of the Greek philosophers. Of no philosophical value itself, its interest lies in the glimpses given of the private life of the philosophers. He treats his subject in two divisions which he describes as the Ionian and the Italian schools. The biographies of the former begin with Anaximander, and end with Cleitomachus, Theophrastus and Chrysippus, the latter begins with Pythagoras, and ends with Epicurus. The Socratic school, with its various branches, is classed with the Ionic, while the Eleatics and sceptics are treated under the Italic. The whole of the last book is devoted to Epicurus, and contains three most interesting letters addressed to Herodotus, Pythochus and Menocleus. The text seems once to have been much fuller than that now in existence. In addition to the *Lives*, Diogenes was the author of a work in verse on famous men, in various metres.

BIBLIOGRAPHY.—*Editor princeps* (1533), H. Hubner and C. Jacobitz with commentary (1828-33), C. G. Cobet (1850), text only. See F. Nietzsche, "De Diogenis Laertii fontibus" in *Rheinisches Museum*, xxiii, xxiv (1868-69), J. Freudenthal, "Zu Quellkunde Diog. Laert." in *Hellenistische Studien*, ii (1870), O. Maass, *De biographis Graecis* (1886), V. Egger *De fontibus Diog. Laert.* (1881). There is an English translation by C. D. Yonge in Bohn's Class Lib.

DIOGENIANUS, of Heraclea on the Pontus (or in Caria), Greek grammarian, flourished during the reign of Hadrian. He was the author of a lexicon (sometimes known as *περιεργονομας* for "industrious poor students") which was perhaps abridged from the great lexicon of Pamphilus of Alexandria (fl. A.D. 50) and other similar works. It formed the basis of the lexicon of Hesychius of Alexandria, described in the preface as a new edition of the works of Diogenianus. We still possess a collection of proverbs under his name (ed. by E. Leutsch and F. W. Schneidewin in *Paroemiographi Graeci*, 1839). Diogenianus was also the author of an anthology of epigrams, of geographical treatises, and of a list (with map) of all the towns in the world.

See H. Weber, *Philol. Suppl.* III, 454 f. (1878); Bursian's *Jahresb.* xvi, 125 (1881).

DIOGNETUS, EPISTLE TO, one of the early Christian apologetes. Diognetus, of whom nothing is known, has expressed a desire to know what Christianity really means—"What is this new race" of men who are neither pagans nor Jews? "What is this new interest which has entered into men's lives now and not before?" The anonymous writer, after attacking idolatry and the ceremonialism of Judaism in the usual way, proceeds in a passage of great eloquence to show that Christians have no obvious peculiarities that mark them off as a separate race. In spite of blameless lives they are hated. Their home is in heaven, while they live on earth. "In a word, what the soul is in a body, thus the Christians are in the world. The soul is enclosed in the body, and yet itself holdeth the body together: so Christians are kept in the world as in a prison-house, and yet they themselves hold the world together." This strange life is inspired in them by the almighty and invisible God, who sent no angel or subordinate messenger to teach them, but His own Son by whom He created the universe. No man could have known God, had He not thus declared Himself. "If thou too wouldst have this faith, learn first the knowledge of the Father. For God loved men, for whose sake He made the world. . . . Knowing Him, thou wilt love Him and imitate His goodness, and marvel not if a man can imitate God: he can, if God will." By kindness to the needy, by giving them what God has given to him, a man can become "a god of them that receive, an imitator of God." No early Christian writing outside the New Testament appeals so much to modern readers. The best edition is that of Otto, *Corpus Apologeticum*, vol. ii (3rd ed. 1879), based on accurate collations of the one ms. which contained this letter and which perished by fire at Strasbourg in 1870.

See also Lightfoot, *Apostolic Fathers* (shorter edition), and (very

conveniently) Kirsopp Lake, *Apostolic Fathers*, vol. ii (in Loeb Classical Library).

DIOMEDEIDAE see ALBATROSS

DIOMEDE ISLANDS, two small adjacent islands in the Bering strait. The larger, Big Diomed, belongs to the U.S.S.R. the other, Little Diomed, is a part of Alaska. They were sighted by Vitus Bering Aug. 16, 1728.

DIOMEDES, Latin grammarian, flourished at the end of the 4th century A.D., author of an extant *Arts grammatica* in three books. The third book is the most important, as containing extracts from Suetonius' *De poetis*. Diomedes wrote about the same time as Charisius (*q.v.*) and used the same sources independently.

The best edition is in H. Keil's *Grammatica Latina*, i, see also C. von Paucker, *Kleinere Studien*, i (1883), on the Latin of Diomedes.

DIOMEDES, in Greek legend, son of Tydeus (*q.v.*), in Homer one of the bravest of the heroes of the Trojan War. In the post-Homeric story, he and Odysseus steal the Palladium, the presence of which within the walls secured Troy against capture (Virgil, *Aeneid*, ii. 164). On his return to Argos, finding that his wife had been unfaithful, he removed to Aetolia, and thence to Daunia (Apulia), where he married the daughter of King Daunus. He was buried or mysteriously disappeared on one of the islands in the Adriatic called after him Diomedede, where his companions were turned into birds (Ovid, *Metam.* xiv. 457 ff.). He was worshipped as a hero in Greece, and on the coast of the Adriatic.

DION (468-354 B.C.), tyrant of Syracuse, the son of Hipparchus, and brother-in-law of Dionysius the Elder. He was a friend of Plato, who had visited the court of the elder Dionysius, and whom Dion now summoned to teach the theory of government to Dionysius' son. But the historian Philistus set Dion at variance with the tyrant, and procured his banishment on a charge of intriguing with the Carthaginians. Dion remained awhile at Athens, but in 357, assembling a small force at Zacynthus, he sailed to Sicily and was received with demonstrations of joy. Dionysius, who was in Italy, returned to Sicily, but was defeated and obliged to flee. Dion himself was soon after banished through the intrigues of Heracleides (356). But the incompetence of the new leader soon led to Dion's recall, Heracleides submitted, and soon afterwards the supporters of Dionysius surrendered. Dion retained the tyranny, but in 354 he was assassinated by Callippus, an Athenian who had accompanied him in his expedition.

See *Lives* by Plutarch and Cornelius Nepos (*c.* Diog. Sic. xvi. 6-20) and in modern times by T. Lau (1860), Freeman, *History of Sicily* (vol. iv) (1894), and Camb. *Anc. Hist.* vol. vi, ch. x with bibliography, see also SYRACUSE and SICILIA. *History*

DIONAEA, see VENUS'S FLY-TRAP

DIONE, cult partner of Zeus of Dodona (Strabo vii. 329). As the partner and wife of Zeus is normally Hera, Dione was variously described in the *Iliad* (v. 370) as mother by Zeus of Aphrodite, in Hesiod (*Theog.* 353) as a daughter of Oceanus.

DIONNE, NARCISSE EUTROPE (1848-1917), Canadian author and librarian, was born at Saint-Denis de la Boutellierie. He studied at St. Anne's college, at the Quebec grand seminary and at Laval university, where he graduated in medicine. He became editor of *Le Courrier du Canada* and then of *Le Journal de Québec*, and in 1892 chief librarian of the Quebec legislature. He has published *Jacques Cartier* (1889), *La Vie de C. F. Panhard* (1894), *Les ecclésiastiques et les royalistes français réfugiés au Canada à l'époque de la révolution, 1791-1802* (1905), *Champlain* (1905), *Québec et Nouvelle France*. *Bibliographie* (4 tom., 1905-12), and in the *Galerie Historique* series of 1910 his chief studies are *Chouart et Radisson*, J. Richard, *Sulpicien, Mgr de Forbin-Janson, Sainte-Anne de la Pocatière and Pierre Bédard*.

DIONNE QUINTUPLETS, five phenomenal daughters of Oliva and Elzire Dionne, born near Callander, Ontario, May 28th, 1934. The attending physician was Dr. Allan Darfoe. These children, weighing collectively but 11½ pounds six days after their premature birth, were rescued from the hazards and handicaps of freak exploitation by the Government of Ontario, which made them King's wards. Against all precedent, the five continued to thrive through childhood. See plate, TWINS and TWINNING.

DIONYSIA, festivals of Dionysus (*qv*). These were numerous and widespread, the most famous being those of Attica, which were (1) the Little or Rustic Dionysia, a festival held in various country places in the month Poseideon (December), characterized by simple, old-fashioned rites, (2) the Lenaia ("festival of Maenads"), in the following month, Gamelion, held at Athens, the chief rites were a festal procession and dramatic performances at the theatre of Dionysus, (3) the Anthesteria (*qv*), in the next month, Anthestherion, (4) The Great or City Dionysia, in Elaphebolion (about the end of March), also accompanied by dramatic performances (see *DRAMA*), and the most famous of all, (5) the Oschophoria ("Carrying of Grape clusters"), in Pyanepsion (about the end of October). The times and what we know of the ritual of these festivals show them to have been originally rites of a kind common in the worship of gods of fertility.

See A. Mommsen, *Feste d. Stadt Athen* (1898), L. R. Farnell, *Cults of the Greek States* (1896-1919) v, ch vi.

DIONYSIUS, pope from 259 to 268. To Dionysius fell the task of reorganizing the Church after the persecution of Valerian. At the protest of some of the faithful at Alexandria, he demanded from their bishop (also called Dionysius) explanations touching his doctrine. He died on Dec. 26, 268.

DIONYSIUS (c. 432-367 B.C.), tyrant of Syracuse, began life as a clerk in a public office, but took advantage of war with Carthage to seize the tyranny (405). The next eight years were spent in strengthening his power. He fortified Epipolae (402), defeated his political opponents, and removed the Greek citizens of Naxos, Catania, and Leontini, handing the cities over to foreign mercenaries and Sikels. His first Punic War (397-396), during which the Greeks besieged Motya, and the Carthaginians Syracuse, ended with a notable victory, and Carthage's power in Sicily was confined to the north-west. His second war in 392 was ended by a treaty greatly in his favour. After 390 he led an expedition against Rhegium and its allied cities in Magna Graecia. In one campaign in which he was joined by the Lucanians, he devastated the territories of Thurii, Croton, and Locri. After a protracted siege he took Rhegium (386), thus making himself the chief power in Greek Italy. At the next Olympic festival (384), whither he sent a splendid embassy, the Athenian Lysias attacked him in a speech (Or. 33) and the crowd pillaged the tents of his envoys.

His third Punic War (383-378) proved disastrous, he suffered a crushing defeat and was obliged to pay an indemnity of 1,000 talents and cede to Carthage the territory west of the River Halykas. He was engaged in another war against Carthage when he died. He had friendly relations with the Spartans, whom he assisted more than once with mercenaries, and two inscriptions record his alliance with Athens (369-367). The success of his tragedy at the Lenaia (367) is probably to be connected with this friendship, though he had frequently competed at Athens he had never till now won a first prize. Dionysius reigned 38 years, and was succeeded by his son Freeman says of him "He had destroyed the freedom of his native city, but he had made it both the greatest city and the greatest power in Europe" (See SICILY and SYRACUSE).

See Diód. Sic. xiii, xiv, xv (the earlier part based on Philistos, *Dionysius' friend and contemporary*), Freeman *Hist. of Sicily* (Vols. iii and iv) (Oxford, 1894), *Com. Anc. Hist.* Vol. vi, ch. v, with bibliography, J. Bass *Dionysius I von Syrakus* (Vienna, 1881), with full refs. to authorities.

His son DIONYSIUS, known as "the Younger," succeeded in 367 B.C. He was driven from the kingdom by Dion (356) and fled to Locri; but during the commotions which followed Dion's assassination, he managed to make himself master of Syracuse. On the arrival of Timoleon he was compelled to surrender and retire to Corinth (343) (Diodorus Siculus, xvi, Plutarch, *Timoleon*).

See SYRACUSE and TIMOLEON, and on both the Dionysii, arts by B. Niese in Pauly-Wissowa's *Realencyklopädie*, v, pt. I (1905).

DIONYSIUS AREOPAGITICUS (or "The Areopagite"), named in Acts xvii, 34 as one of those Athenians who believed when they had heard Paul preach on Mars Hill. Beyond this men-

tion our only knowledge of him is the statement of Dionysius bishop of Corinth (fl. 171), recorded by Eusebius (*Church Hist.* iii, 4, iv, 23), that this same Dionysius the Areopagite was the first "bishop" of Athens. Some hundreds of years afterwards his name was attached to a number of anonymous theological writings of unknown origin. These were destined to exert enormous influence on mediaeval thought, and their form led to a great development of the personal legend of the original Dionysius (see for example, "The Life and Passion of the Most Holy Dionysius," by Hilwin, Abbot of St. Denys, printed in Migne, *Patrologia Latina*, vol. 106).

The author, date and place of composition of these writings are alike unknown. External evidence precludes a date later than 500, the internal evidence from the writings themselves precludes any date prior to 4th-century phases of Neo-platonism, while the first certain dated reference to them is at the Council of Constantinople in 533. The extant writings of the Pseudo-Areopagite are (a) *Περὶ τῆς οὐρανίας ιεραρχίας, Concerning the Celestial Hierarchy*, in 15 chapters, (b) *Περὶ τῆς ἐκκλησιαστικῆς ιεραρχίας, Concerning the Ecclesiastical Hierarchy*, in 7 chapters, (c) *Περὶ βέλων ὀνομάτων, Concerning Divine Names*, in 13 chapters, (d) *Περὶ Μυστικῆς θεολογίας, Concerning Mystic Theology*, in five chapters, (e) ten letters addressed to various worthies of the apostolic period. They are all of great interest, first as a striking presentation of the heterogeneous elements that might unite in the mind of a gifted man in the 5th century, and secondly, because of their enormous influence upon subsequent Christian theology and art. Their ingredients—Christian, Greek, Oriental and Jewish—are united into an organic system, not crudely mingled. Perhaps theological philosophic fantasy has never constructed anything more remarkable. The system of Dionysius was a proper product of its time—lofty, and apparently complete.

His constructive principles the writer owed to Hellenism in its last great philosophical creation, Neo-platonism, since the general principle of the transmission of life from the ultimate Source downward through orders of mediating beings unto men might readily be adapted to the Christian God and his ministering angels. Pseudo-Dionysius had lofty thoughts of the sublime transcendence of the ultimate divine Source. That Source was not remote or inert, but a veritable Source from which life streamed to all lower orders of existence,—in part directly, and in part indirectly as power and guidance through the higher orders to the lower. Life, creation, every good gift, is from God directly, but his flaming ministers also intervene to guide and aid the life of man, and the life which through love floods forth from God has its counterflow whereby it draws its own creations to itself. God is at once absolutely transcendent and universally immanent. To live is to be united with God, evil is the non-existent, that is, severance from God.

The transcendent Source, as well as the universal immanence, is the True God. Between that and men are ranged the three triads of the celestial hierarchy: Seraphim, Cherubim and Thrones, Dominations, Virtues, Powers, Principalities, Archangels, Angels. Collectively their general office is to raise mankind to God through purification, illumination and perfection, and to all may be applied 'he term angel. The highest triad, which is nearest God, contemplates the divine effluence, and reflects it onward to the second, the third, and more specifically angelic triad, immediately ministers to men. The sources of these names are evident: seraphim and cherubim are from the Old Testament, later Jewish writings gave names to archangels and angels, who also fill important functions in the New Testament. The other names are from Paul (Eph. i, 21, Col. i, 16).

Such is the system of Pseudo-Dionysius, as presented mainly in *The Celestial Hierarchy*. That work is followed by *The Ecclesiastical Hierarchy*, its counterpart on earth. What the primal True Godhead is to the former, Jesus is to the latter. The ecclesiastical hierarchy likewise is composed of triads. The first includes the symbolic sacraments: Baptism, Communion, Consecration of the Holy Chrism. Baptism signifies purification, Communion signifies enlightening, the Holy Chrism signifies perfecting. The second is made up of the three orders of Bishops, Presbyters and

of a *Chronicle* narrating the history of the world from the creation to the year A.D. 774-775, but on the completion of its publication by M. Chabot in 1895, Noldeke (*Vienna Oriental Journal*, x, 160-170), and Nau (*Bulletin critique*, xvii, 321-327), clearly proved that the chronicle was the work not of Dionysius but of an earlier writer, a monk of the convent of Zakun near Amid (Diarbekr) on the upper Tigris. Though the author had limited intelligence and little historical skill, the last part of his work has considerable value as a contemporary account of events during the middle of the 8th century.

See W. Wright, *Hist. of Syriac Literature* (1894), and Chabot's introduction to his translation of pt. iv of the *Chronicle*.

DIONYSIUS THRAX (so called because his father was a Thracian), the author of the first Greek grammar, flourished about 100 B.C. He was a native of Alexandria, where he attended the lectures of Aristarchus, and afterwards taught rhetoric in Rhodes and Rome. His grammar, which we possess (though probably not in its original form), begins with the definition of grammar and its functions. Dealing next with accent, punctuation marks, sounds and syllables, it goes on to the eight parts of speech and their inflections. No rules of syntax are given, and nothing is said about style. The authorship of Dionysius was doubted in the middle ages, and in modern times its origin has been attributed to the ecclesiastical college founded by Constantine the Great, which existed until 730. But there seems no reason for doubt, the great grammarians of imperial times (Apollonius Dyscolus and Herodian) knew the work in its present form, although additions and alterations may have been made later. Dionysius also wrote commentaries on Homer and Hesiod and various other works, including an account of Rhodes, and a collection of *Makrura* (literary studies), to which the considerable fragment in the *Stromata* (v. 8) of Clement of Alexandria probably belongs. The grammar, first edited by J. A. Fabricius from a Hamburg ms., was published in his *Bibliotheca Graeca*, vi (ed. Harles). An Armenian translation, belonging to the 4th or 5th century, containing five additional chapters, was published with the Greek text and a French version, by M. Ciriach (1830).

Editions, with scholia, by I. Bekker in *Anecdota Graeca*, ii and G. Uhlig (1884), reviewed exhaustively by P. Egenolf in *Bursian's Jahresbericht*, xlv (1888); Scholia, ed. A. Filargel (1901), Eng. transl. J. Davidson, 1894, see also W. Roschdanz, *De Dionysii Thracis interpretibus veteribus* (1874); J. E. Sandys, *Hist. of Classical Scholarship*, i (1906).

DIONYSUS, in Greek mythology originally a nature god of fruitfulness and vegetation, especially of the vine, hence, disjunctively, the god of wine. [Gr. *Διόνυσος*, *Διόνυσος*, Thracian, *Zōnnyxos*, Phrygian, *Dionusis* extremely doubtful, *Idon*, name of Thracio-Phrygian sky god resembling Zeus, *revr*, possibly akin to Lat. *nurus*, Gr. *νύξ*, and may mean "child" or "son", hence perhaps "son of God".] The names *Bacchus* (*Bákxos*, in use among the Greeks from the 5th century), *Sabazus*, and *Bassareus*, are also Thracian names of the god. All are of doubtful significance, for various interpretations of these and other cult-titles. See O. Gruppe, *Griechische Mythologie*, ii, pp. 1408, 1523, especially the notes.]

There seems little doubt that he is a Thracio-Phrygian deity, introduced into Greece from Thracian or possibly from both Thracian and Phrygia, and blending with the native gods of similar character, e.g., *Iacchus* or *Ploutos* in Homer, notwithstanding the frequent mention of the use of wine. Dionysus is never mentioned as its inventor or introducer, nor does he appear in Olympus. He is the first who calls wine the gift of Dionysus. On the other hand, he is called *oikos* in the *Iliad* (v. 132, *oikos*), i.e., "agony" in the sense that it is already the organic character of his worship was introduced in his native country, his worshippers sought to become possessed by it, assumed to him by wild dancing and perhaps the use of intoxicants, in Greece this was much toned down. According to the usual tradition he was born at Thebes and was the son of Zeus and Semele, the daughter of Cadmus. Before the child was mature, Zeus appeared to Semele, whose rime is dimly the Phrygian for "earth" (*Ermitis*), for her request in his mai was, is god of lightning, by which she was killed, but the infant was saved from the flames by Zeus (for *Hermes*). Zeus took him up, enclosed him within his arm (which in the *Iliad* it came to maturity and then brought him to the light, so that he was *tautē* name of the god and of a hymn in his honour, which perhaps is really to be connected with Phrygian *diitara*, a tomb. (See Calder in

Class. Rev., xxvii, p. 11, ff. xlv, p. 161 ff.) Dionysus was then conveyed by Hermes to be brought up by the nymphs of Nysa, a purely imaginary spot. As soon as Dionysus was grown up, he started on a journey through the world, to teach the cultivation of the vine and spread his worship among men. While so engaged he met with opposition, even in his own country, as in the case of Pentheus, king of Thebes, who opposed the orgiastic rites introduced by Dionysus among the women of Thebes, and, having been discovered watching one of these ceremonies, was mistaken for some animal of the chase, and slain by his own mother. A similar instance is that of Lycurgus a Thracian king, from whose attack Dionysus saved himself by leaping into the sea, where he was kindly received by Thetis. Lycurgus was blinded by Zeus and soon died, or became leared the cultivation of the vine and mistaking him for a vine. At Orchomenus, the three daughters of Minyas refused to join the other women in their nocturnal orgies, and for this were transformed into birds. (See *Agriostia*.) These and similar stories may point to the vigorous resistance offered to the introduction of the mystic rites of Dionysus or to some ceremony in which the god, or a priest representing him, was killed and probably brought to life again. See below. On the other hand, when the god was received hospitably he repaid the kindness by the gift of the vine, as in the case of Icarus of Attica. (See *Ergaster*.)

The worship of Dionysus continued to flourish in Asia Minor, particularly in Phrygia and Lydia. His cult is closely associated with that of numerous Asiatic deities, as Sabazus (*qv*), and from the time of Alexander, he appears as conqueror of India. The other incidents in which he appears in a purely theatrical character are his transformation into dolphins the Tyrrhenian pirates who attacked him, and his part in the war of the gods against the giants. The adventure with the pirates occurred on his voyage to Naxos, where he found Ariadne abandoned by Theseus. At Naxos he traded (probably a Cretan mother goddess) was associated with Dionysus as his wife, and their marriage was annually celebrated by a festival. Having compelled all the world to recognize his divinity, he descended to the underworld to bring up his mother. Like most deities connected with vegetation, Dionysus, at least in Thracian, died and rose again. This is reflected principally in Orphic mythology, not in normal Greek belief. Zeus had by Persephone a wonderful child Zagreus. He was brought up secretly, watched over by Curetes, but the jealous Hera discovered where he was, and sent Titans to the spot, who, finding him at play, tore him to pieces, and cooked and ate his limbs, while Athena gave his heart to Zeus. This myth is probably to be connected with the savage rite of *emophagia* (eating of raw flesh) in the worship of Dionysus, in which a victim, perhaps originally human in some cases, incarnating the god, was torn in pieces and eaten by his worshippers. He is variously reconciled with the tale of Semele. (See also *Thracian*.)

Dionysus further possessed the prophetic gift, and at Delphi was received by the priesthood of Apollo on almost equal terms. His followers included spirits of fertility, as the satyrs, and in his ritual the phallus was prominent. He often takes bestial shape, and is associated with the panther, the lion, the snake, the tiger, the ass, the goat, and sometimes also the dolphin. His personal attributes are an ivy wreath, the thyrsus (*qv*), and the kantharos, a large two-handled goblet. His later representations in art show a youth of soft, rather feminine form, occasionally an infant, but the earlier type is a bearded man. His title *Dendrites* ("he of the tree") arises most probably from his functions as a god of the productivity of nature, not of the vine only.

DIOPHANTINE EQUATIONS or **DIOPHANTINE ANALYSIS**, is the name given to that branch of the Theory of Numbers which treats the problem of finding the solutions, in whole numbers (integers) or rational fractions, of one or more conditional algebraic equations whose coefficients are rational. For example, the problem of finding the whole numbers x and y satisfying $x^2 + y^2 = 10$ is a Diophantine problem and this equation is called Diophantine. Our topic takes its name from the Greek mathematician Diophantus who probably flourished about the middle of the 3rd century A.D. He treated a number of problems such as the following to find three rational numbers such that the product of any two added to the sum of these product added to any one of them gives a square.

Following our definition of it, the subject really includes much material from a number of topics in the theory of rational integers, usually discussed separately, such as *Waring's Theorem*, the *Theory of Congruences*, the *Theory of Quadratic and Higher Forms* (see *NUMBERS, THEORY OF*). In view of this it is not wise to confine ourselves here to the consideration of the parts of our subject which have not been so definitely classified.

Diophantus solved the problem of finding formulas giving all the right triangles whose sides are integral. To obtain these we may reason as follows. Let the triangle have the sides x, y and z , then we are to find an expression for all the positive integers which satisfy

$$(1) \quad x^2 + y^2 = z^2$$

It may be shown that the formulas

$$x = 2kmn, \quad y = k(m^2 - n^2), \quad z = k(m^2 + n^2) \quad (2)$$

where k is an arbitrary positive integer, give all the positive integral solutions of (1).

A generalization of (1), namely the equation

$$x^{2n} + y^{2n} = z^{2n}, \quad n > 2,$$

has received a great deal of attention (see FERMAT'S LAST THEOREM).

A particular topic in Diophantine Analysis which is now generally referred to as the theory of quadratic forms, treats, by the use of linear transformation, the problem of solving the equation

$$ax^2 + bxy + cy^2 = m,$$

in integers x and y for a, b and c given integers. (See NUMBERS, THEORY OF.) An older method involves the use of continued fractions.

Continued fraction methods are also known for expressing a prime p in the form $x^2 + my^2$, $m > 0$, for various classes of values of p and m . Such a method was first derived by Adrian M. Legendre (1824) for $m = \pm 1$ and $p = r$ (mod 4).

We now consider homogeneous quadratic equations. Using Joseph L. Lagrange's results on $x^2 - Dy^2 = m$, Legendre (1768) found the elegant result that if each of the positive integers a, b and c has no square factor, no two have a common factor and if there exist integers λ, μ, ν such that

$$\frac{a\lambda^2 + b}{c}, \quad \frac{a\mu^2 - b}{c}, \quad \frac{c\nu^2 - a}{c}$$

are all integers then $ax^2 + by^2 = cz^2$ has integral solutions not all zero and if the three conditions are not all satisfied then there are no integral solutions. Adolph Mayer (1884) gave a criterion that

$$(4) \quad ax^2 + by^2 + cz^2 + d^2w^2 = 0$$

with a, b, c and d integers none zero, without square factors and such that no three have a common factor, has solutions in integers. He also arrived at the result that

$$(5) \quad ax^2 + by^2 + cz^2 + d^2w^2 + e^2v^2 = 0$$

is solvable in integers not all zero if the coefficients are odd and not all of the same sign. L. E. Dickson (1930) noted that Mayer's arguments concerning (4) and (5) were not complete. Thanks to his contributions (1930, 1939) and those of H. Hasse (1933) and L. J. Mordell (1931) the complete criteria for the solution of (4) for any nonzero integers a, b, c, d has been obtained. Also Dickson (1930) gave the first complete proof that (5) is always solvable in integers if not all the nonzero integers a, b, c, d , and e are of like sign. Hasse (1933) obtained a number of elegant results concerning quadratic Diophantine equations by the use of Congruences. An example is the theorem that the equation is solvable in integers if and only if

$$\sum a_i x_i x_j \equiv 0 \pmod{M}$$

is properly solvable for all integers M . In this statement the term properly solvable means that $(x_i, M) = 1$ for each i . E. T. Bell (1933) and Morgan Ward (1933) gave, when any exist, all the solutions of

$$A_1 x_1^{a_1} x_2^{a_2} \dots x_n^{a_n} = B_1 y_1^{b_1} y_2^{b_2} \dots y_k^{b_k}$$

In parametric form.

Th. Skolem (1938) gave a number of applications of the theory of Algebraic Numbers (see NUMBERS, THEORY OF) to Diophantine problems. In this connection he examined the equation

$$(6) \quad N(\alpha x_1 + \dots + \alpha_n x_n) = a$$

where the α_i 's are integers in an algebraic field K of degree n and $N(\omega)$ denotes the norm of ω in K , a being a rational integer, and treats by the use of units in K the problem of finding other sets of solutions of (6), having given one set, as well as methods for determining if any set exists.

It is clear that if we have any Diophantine equation and we know all its rational solutions, then these solutions will include all the integral solutions. However, Dickson (1920) pointed out many cases in the literature where formulas had been given for finding all the rational solutions of equations and no method had been supplied for picking out any integral ones. In view of this he considered the problem of finding the integral solutions of

$$(7) \quad ax^2 + bxy + cy^2 = wz$$

in integers x, y, w, z , with a, b and c given integers, and gave a complete solution. Generalizations to forms of any degree were obtained by Wahlen (1924) and Skolem (1938). The special case of (7) namely

$$ax^2 + bxy + cy^2 = x^n$$

has been treated by many writers. Lagrange (1766) and Euler (1770) obtained an infinitude of solutions of

$$x^2 - my^2 = z^n$$

with m an integer. Morgan Ward (1935) applied the theory of quadratic algebraic fields to (8) and gave a set of formulas for its complete solution.

Considerable literature has resulted from the examination of equations of the type

$$f(x, y) = c$$

where $f(x, y)$ is a polynomial in x and y with integral coefficients and c is an integer $\neq 0$. These developments seem to have had their beginning in the work of C. Runge (1887), who proved, moreover, older results the following one: "Let $f(x, y)$ be a polynomial with integral coefficients irreducible in the rational field, the homogeneous part of f of highest degree not being the power of an irreducible polynomial. Then $f(x, y) = c$ has only a finite number of solutions in rational integers." This was followed by the work of A. Thue (1909) who proved the following celebrated theorem: "If $f(x, y)$ is a homogeneous polynomial with integral coefficients, irreducible in the field of rational numbers and of degree > 2 , and c is an integer $\neq 0$, then $f(x, y) = c$ has only a finite number of integral solutions."

In view of the above results we may consider

$$f(x_1, x_2, \dots, x_n) = c$$

where f is a homogeneous polynomial in x_1, x_2, \dots, x_n with integral coefficients, of degree n and irreducible in the rational field ϵ being an integer. We know from the theory of units in an algebraic field that for $k = n$ and $c = 1$ there exist equations of this type with an infinity of integral solutions. On the other hand, if $k = 2$, $n > 2$, Thue's theorem states that there cannot be more than a finite number of solutions. An interesting question is, how far must k be increased to obtain equations of this type with an infinity of solutions? If $n = 3$ we have $k = 3$. Related to this is a conjecture which Euler (1772) made, and which amounts to a generalization of Fermat's Last Theorem. He stated that, in his opinion, the equation

$$(9) \quad x^n + y^n + z^n = 1$$

has no integral non-zero solutions for $n < k < n$. The particular case $n = 4$ has been much studied. For $k = 2$ it is known that there are no such solutions, for $k = 4$ some solutions have been found but for the difficult case $k = 3$ we as yet (1946) cannot say whether or not solutions exist. Ward (1945) proved that there is no non-zero solution of (9) with $k = 3$, $n = 4$ and $y < 10000$.

The problem of finding rational solutions of certain types of equations has been successfully attacked by the use of geometric methods. This is often expressed as the problem of finding the rational points on a curve or surface. The curves

$$f(x, y) = 0 \text{ or } f(x, y, z) = 0$$

in homogeneous co-ordinates, are classified for arithmetical purposes according to their genus (see Curve), the coefficients of the equations being integral. Two curves are called equivalent when they are connected with each other by a birational transformation with rational coefficients. Thus two curves

$$f_1(x, y) = 0, f_2(x, y) = 0$$

are equivalent if the co-ordinates x, y are rationally expressible with rational coefficients in terms of ξ, η , and conversely. If a curve is of genus zero, it was shown by David Hilbert and A. Hurwitz (1890) and Jules H. Poincaré (1901) that it is equivalent to a straight line or a cone, from which the theory of the rational points on the original curve is easily derived.

For a curve of genus unity, Poincaré (1901) also proved that if it has a rational point, it is equivalent to a curve of the third degree, and, in particular, the cubic is equivalent to a curve whose equation can be written in the Weierstrass normal form

$$(10) \quad y^2 = 4x^3 - g_2x - g_3$$

The latter statement was proved by Mordell in 1912. Poincaré (1901) and A. Hurwitz (1917) noted that the equation (10) could be given in parametric form by the use of Weierstrass' elliptic p functions (see ELLIPTIC FUNCTIONS) so that

$$(11) \quad x = p(u), \quad y = p'(u)$$

It was proved by Mordell (1922) with the use of these ideas that all the rational points on (10) could be found from a finite number of rational points, so that, using (11), if u_1, u_2, \dots, u_n satisfy (10) then all rational points are given by $mu_1 + mu_2 + \dots + mu_n$, where the m 's are integers.

Quite recently the subject of the rational solutions of cubic ternary equations has been extensively investigated and general results obtained, by the use of both geometric and algebraic methods. B. Segre (1943) took up this type of problem using geometric ideas, and proved that if $f(x, y, z)$ is a given cubic polynomial in x, y, z with rational coefficients which is not expressible as a polynomial in a single linear function of x and y , the equation

$$a^2 = f(x, y, z)$$

has an infinity of solutions in x, y and z . From this he showed that an indeterminate ternary cubic equation which cannot be reduced to an equation involving less than three variables has either no rational solution or an infinity of rational solutions, and each case is possible. Mordell (1943) obtained similar results using algebraic methods exclusively.

In spite of the fact that our subject has been attacked by some of the most powerful weapons known to analysis, geometry and abstract algebra, it contains vast domains which have hardly been touched by investigators, and offers great opportunities for a mathematical pioneer.

DIOPHANTUS, of Alexandria, Greek algebraist, probably flourished about the middle of the 3rd century. Not that this date rests on positive evidence. But we gather from a passage of Michael Psellus (*Diophantus*, ed. P. Tannery, II, p. 38) that he was not later than Anatolius, bishop of Laodicea from AD 270, while he is not quoted by Nicomachus (fl. c. AD 100), nor by Theon of Smyrna (c. AD 130), nor does Greek arithmetic as represented by these authors and by Iamblichus (early 4th century) show any trace of his influence, facts which can only be accounted for by his being later than those arithmeticians at least who would have been capable of understanding him fully. On the other hand he is quoted by Theon of Alexandria (who observed an eclipse at Alexandria in AD 365), and his work was the subject of a commentary by Theon's daughter Hypatia (d. 415). The *Arithmetica*, the great treatise on which the fame of Diophantus rests, purports to be in 13 books, but none of the Greek mss which have survived contain more than six (though one has the same text in seven books). They contain, however, a fragment of a separate tract on *Polygonal Numbers*. The missing books were apparently lost early, for there is no reason to suppose that the Arabs who translated or commented on Diophantus ever had access to more of the work than we now have. The difference in form and content suggests that the *Polygonal Numbers* was not part of the larger work. On the other hand the *Porisms*, to which Diophantus makes three references ("we have it in the *Porisms* that..."), were probably not a separate book, but were embodied in the *Arithmetica* itself, whether placed all together or spread over the work in appropriate places. The "*Porisms*" quoted are interesting propositions in the theory of numbers, one of which was clearly that the difference between two cubes can be resolved into the sum of two cubes.

Among the great variety of problems solved are problems leading to determinate equations of the first degree, in one, two, three or four variables, to determinate quadratic equations and to determinate equations of the first degree in one or more variables, which are, however, transformed into determinate equations by arbitrarily assuming a value for one of the required numbers. Diophantus being always satisfied with a rational, even if fractional, result, and not requiring a solution in integers. But the bulk of his work consists of problems leading to indeterminate equations of the second degree, and these universally take the form that one or two (and never more) linear or quadratic functions of one variable x are to be made rational square numbers by finding a suitable value for x . A few problems lead to indeterminate equations of the third and fourth degrees, an easy indeterminate equation of the sixth degree being also found. The general type of problem is to find two, three or four numbers such that different expressions involving them in the first and second, and sometimes the third, degree are squares, cubes, partly squares and partly cubes, etc., e.g., to find three numbers such that the product of any two added to the sum of those two gives a square (III 15), to find four numbers such that, if we take the square of their sum + or - any one of them singly, all the resulting numbers are squares (III 19), to find 10 numbers such that their product is 1 or -1 (I 18 m gives a cube (IV 25), to find three squares such that their continued product is reduced to any one of them (I 10, m is q ar. II 21). Book VI contains problems of finding rational or integral solutions to such that different functions of the parts (the sides and the area) are squares. A word is necessary on Diophantus' notation. He has only one symbol (written somewhat like a final sigma) for an unknown quantity, which he calls *arithmos* (defined as "an undetermined number of units"), the symbol may be a contraction of the initial letters *ar*, as $\alpha\delta$, κ , λ , etc., are for the powers of the unknown (δ for square, λ for cube, κ for fourth power, etc.). The only other algebraic symbol is Λ for "plus" plus being expressed by merely writing terms one after another. With one symbol for an unknown, it will easily be understood that "more than" is not a doubtful assumption, for the required number, or expression, in the unknown which are at once seen to satisfy some of the conditions, leaving only one or two to be satisfied by the particular value of x to be determined. Often assumptions are made which lead to the final equation in x which cannot be solved "rationally," i.e., would give negative, surd or imaginary values, Diophantus then traces how each element of the equation arose and formulates the auxiliary problem of determining how the assumptions must be corrected so as to lead to an equation in which x has to do duty twice, for different unknowns, in one problem. In general his object is to reduce the final equation to a simple one by making such an assumption for the side of the square or cube to which the expression in x is to be equal as

will make the necessary number of coefficients vanish. The book is valuable also for the propositions in the theory of numbers, other than the "*porisms*," stated or assumed in it. Thus Diophantus knew that no number of the form $8n+7$ can be the sum of three squares, "it must not be odd" (i.e., no number of the form $4n+3$, or $4n-1$, can be the sum of two squares), and goes on to add, practically, the condition stated by Fermat, "and the double of it increased by one when divided by the greatest square which measures it must not be divisible by a prime number of the form $4n-1$," except for the omission of the words "when divided by measures it."

BIBLIOGRAPHY—The first to publish anything on Diophantus in Europe was Rafael Bombelli, who embodied in his *Algebra* (1572) all the problems of Books I-IV and some from Book V interspersing them with his own problems. Next Xylander (Wilhelm Holzmann) published a Latin translation (Basle, 1575), an altogether meritorious work, especially having regard to the difficulties he had with the text of his ms. The Greek text was first edited by C. G. Bachet (*Diophanti Alexandrini arithmeticonum libris sex, et de numeris multisquis liber unus, nunc primum graeco et latine editi atque absolutissimis commentariis illustrati* Lutetiae Parisiorum MDCXXI). A reprint of 1670 is valuable because it contains Fermat's famous notes, so far as the Greek text is concerned it is much inferior to the other. There are two German translations, one by Otto Schulz (1882) and the other by G. Wertheim (Leipzig, 1890), and an English edition in modern notation (T. L. Heath, *Diophantus of Alexandria: A Study in the History of Greek Algebra* (Cambridge 1885 second edition 1910). The Greek text has now been definitively edited (with Latin translation, scholia, etc.) by Tannery (Teubner, vol. 1 1893, vol. 2 1895). General accounts of Diophantus' work are to be found in the histories of mathematics and in Pauly Wissowa, more elaborate analyses are those of Nesselmann (*Die Algebra der Griechen*, 1842) and G. Loria (*La scienza esatte nell' antica Grecia*, 1914, pp. 845-919) (T. L. H.)

DIOPHANE, an important member of the pyroxene ($q\gamma$) group of rock-forming minerals.

DIOPTR. A unit of measurement used in optics to measure the power of a lens or lens system. The power of a lens is the reciprocal of its focal length, and when the focal length is expressed in metres the power of the lens is in dioptries. Thus a lens whose focal length is one metre has a power of one diopter, a lens of focal length 50 cm (1/2 metre) a power of 2 dioptries, a lens of focal length 2 metres 1/2 diopter and so on. (See *Lenses*.)

DIORITE, the name given by R. J. Haüy to a family of rocks of granitic texture, composed of plagioclase feldspar and hornblende. Since they are richer in the dark-coloured ferromagnesian minerals, they are usually gray or dark gray and have a higher specific gravity than granite. They also rarely show visible quartz. But there are diorites of many kinds, since the name applies rather to a family of rocks than to a single species. Some contain biotite, others augite or hypersthene, many have a small amount of quartz. Orthoclase is rarely entirely absent, and when it is common the rock becomes a monzonite. It is rare to find the pure types of "hornblende diorite," "augite diorite," etc., but in most cases the rocks contain two or more ferromagnesian silicates, and such combinations as "hornblende-biotite diorite" are commonest in nature.

The feldspar of the diorites ranges, in composition, from oligoclase to labradorite and is often remarkably zonal, the external layers being more calcic than the internal. Small fluid inclusions and black grains probably iron oxides often occur in it in great numbers. Weathering produces epidote, calcite, sericite and kaolin. The matrix is always brown or yellow, the hornblende usually green, but sometimes brown or yellow like biotite in those diorites which have almost no hornblende. The matrix is nearly always green but sometimes has a reddish tinge, brownish and hypersthene have then a green and brown shades. Epidote iron oxides and zircon are almost invariably present. Epidote, quartz and orthoclase are usually observed, calcite, chlorite, microcline, apophyllite and bastite are secondary. The structure is not essentially different from that of granite. The ferromagnesian minerals crystallize comparatively early and have some idiomorphism, the feldspar usually follows and only in part shows good crystalline outlines. Orthoclase and quartz, if present, are last to separate out, and fill the spaces between the other minerals, often they interpenetrate to form micropegmatite. In many diorites the plagioclase feldspar has crystallized before the hornblende, which consequently has less perfect outlines and forms irregular plates which enclose sharply formed individuals of feldspar, thus producing the ophitic structure (common also in the dolerites). More rarely biotite and augite exhibit the same relations to the plagioclase. Orbicular structure also occasionally appears in these rocks, in fact the orbicular diorite of Corsica (also called "napoleonite")

[*q v*] or "corate") was for a long time the best known example of this structure. Occasionally diorites have a parallel banded or foliated structure, but these must not be in any manner confounded with the epidiorites, which are metamorphic rocks without conspicuous foliation.

Diorites must also be distinguished from hornblende gabbros, which contain more basic feldspars, rarely quartz and occasionally olivine, but the boundary lines between diorites and gabbros are admittedly somewhat vague, e.g. some authors would call rocks gabbro which others would regard as augite diorite. The hornblendites differ from the diorites in containing little feldspar, and consist principally of hornblende. Among varietal designations given to rocks of the diorite family are "basanite" for an augite-diorite with or without quartz (from the Schemnitz district), "granodiorite" for a quartz-hornblende diorite (essentially the same as tonalite) from California, etc., "ornate" for a hornblende-diorite rich in feldspar, from Sweden (J S F).

DIOSCOREACEAE, a family of monocotyledonous plants which includes the yam (*q v*), the black bryony (*Tamus communis*), and the elephant's foot (*q v*). There are nine genera and about 650 species, all climbing herbs or shrubs with tubers or rhizomes. The flowers are small, usually inconspicuous, unisexual or perfect, usually regular, the parts in threes. The fruits are for the most part of a three-winged capsule, the seeds mostly winged. The family is economically important, as many species of *Dioscorea* are cultivated for their edible tubers, those of the greater yam (*D. alata*) sometimes attaining a weight of 40 lb. Other cultivated species are *D. batatas*, *D. esculenta*, *D. cayenensis*, *D. bulbifera*, *D. pentaphylla* and *D. triloba*.

For a monographic treatment see R. Knuth, *Dioscoreaceae* Phänomenon 87 (iv, 43), 1-298 fig. 1-69 (1924).

DIOSCORIDES, PEDANIOS (fl. c. A.D. 50), Greek medical man, born in Cilicia, served in the army of Nero. He was the first to establish medical botany as an applied science. He is known through his *Materia Medica*. It details the properties of about 600 medicinal plants and describes animal products of the tetter and medicinal value. He was a contemporary of Pliny.

See F. H. Garrison, *Introduction to the History of Medicine*, pp. 100-110, 4th ed. rev. (1929).

DIP, in magnetism (see TERRESTRIAL MAGNETISM), the angle made by the direction of the earth's magnetic field and the horizontal is the angle of dip, commonly called the dip. In astronomy (*q v*) and surveying (*q v*) the dip of the horizon is the angular distance between the true horizon and the apparent horizon, due to the observer's elevation. In geology (*q v*) the angle which the line of maximum slope of a stratum makes with the horizontal.

DIPAVAMSA, a poem ("History of the Island") composed in Ceylon in the Pāli language, relating the history of Buddhism in India and its propagation in Ceylon. It belongs to the 4th century A.D., and is the earliest example of a purely historical composition relating to India. It contains 22 chapters, and begins with the enlightenment of Buddha, the immediately following events and his three legendary visits to Ceylon. Then follows the genealogy of the kings of Buddha's ancestry from the first king of this cycle (*kāpa*) down to Buddha and his son Rāhul. The historical portion begins with chapter 4, the history of Buddhism in the Magadha kingdom down to the third council in the reign of Asoka. From this point it continues with the history of Ceylon, the settlement of the island by king Vijaya, the subsequent kings down to Devānampiya Tissa, under whom Buddhism was introduced by Asoka's son Mahinda, with a continuation of the history of the island ending with king Mahāsena at the beginning of the 4th century A.D.

As the *Dipavamsa* is the oldest connected account of Buddhism and of contemporary secular events in India for the first three centuries of its history, it is important to determine if possible in what sense it can be called historical. There are two circumstances to be first considered, the fact that its record of events (apart from purely local Sinhalese history) was compiled in India, and consequently cannot be treated as the composition or invention of a Sinhalese author, and secondly that it corresponds in important features with the Purāṇas. The Purāṇas, like the *Dipavamsa*, contain genealogies of kings which are traced up to the purely legendary beginnings of the cycle, and recent study has not only shown that the Purāṇas contain genealogies belonging to actual lines of

kings, but further that in the case of the Māgadhī kings between Buddha and Asoka both the Purāṇas and the *Dipavamsa* rest on a common historical basis. This is further corroborated by the lists found in Jain works. What we possess is not a historical record in the modern sense, for the chronicles, recorded events uncritically and accepted legends about quite historical persons. This is very different from free invention. What we have to guard against is not deliberate romancing, but faults due to the very defective means of transmitting and recording events, and the unhistorical attitude of the compilers. The probable mode of composition has been most closely studied by H. Oldenberg, who first edited the *Dipavamsa*, and by W. Geiger, who has edited the latter chronicle, the *Mahāvamsa*. A native commentary (*tiṭṭa*) on the *Mahāvamsa*, was compiled about A.D. 1000. References in it show that at that time there was in existence a Sinhalese historical work which formed part of the great Sinhalese commentary on the Buddhist scriptures. The existence of this Sinhalese commentary at least as early as the 4th century A.D. is known from frequent references found in the existing Pāli commentaries. It was on the basis of this work in Sinhalese that the *Dipavamsa* was compiled, and its repetitions and the disjointed arrangement of various passages show that it must have been compiled from just such a source. The main details of the work correspond so closely with those in the Indian records (the Purāṇas and Buddhist Sanskrit works) that it is clear that they are of Indian origin. This Sinhalese work must have at first ended with the introduction of Buddhism into Ceylon by Mahinda, but it appears to have been later on extended to the reign of Mahāsena. This is the period covered by the *Dipavamsa*, and this work is probably a recension and adaptation of the whole of the Sinhalese work. These conclusions are essentially the views of Geiger, who has summarized his results about both the *Dipavamsa* and the *Mahāvamsa* in his translation of the latter work. References will also be found here to the criticisms of R. O. Franke, whose attitude on the historical value of the chronicles is one of complete scepticism. (See MAHĀVAMSA).

BIBLIOGRAPHY—H. Oldenberg (ed and tr.), *The Dipavamsa* (1879), W. Geiger (tr.), *The Mahāvamsa* (1912), M. Winternitz, *Geschichte der Indischen Literatur*, vol. 2 (1920).

DIP CIRCLE. An instrument used for measuring the magnetic dip. It consists essentially of a magnetic needle pivoted at the centre of a graduated metal circle. The circle is mounted with its plane vertical and the axis about which the needle turns horizontal. If such an instrument is placed with the plane of the circle in the magnetic meridian the needle will be in the direction of the earth's magnetic field. See TERRESTRIAL MAGNETISM.

DIPHENYL or BIPHENYL, an aromatic hydrocarbon found in that fraction of the coal-tar distillate boiling between 240°–300° C. from which it may be obtained by warming with sulphuric acid, separating the acid layer and strongly cooling the undissolved oil. It crystallizes in plates (from alcohol) melting at 70–72° C., and it boils at 254° C. It is sometimes called phenyl benzene, having the structure $C_6H_5.C_6H_5$. It may be prepared by passing benzene vapour through a red-hot tube, by the action of sodium or bromobenzene dissolved in ether, by the action of stannous chloride on phenyldiazonium chloride, by the decomposition of phenyldiazonium sulphate with warm benzene or with alcohol and copper powder, or a yield of 82% of diphenyl is obtained by heating iodobenzene with copper powder at 320° C. The principal use of diphenyl itself is as a heat-transfer fluid, either alone or in the form of its eutectic mixture (Dowtherm A) with diphenyl ether ($C_6H_5.O$). (See also BENZIDINE).

DIPHILUS, of Sinope, poet of the New Attic Comedy and contemporary of Menander (342–291 B.C.). Most of his plays were written and acted at Athens, but he led a wandering life and died at Smyrna (Athenaeus xii, pp. 579, 583). He is said to have written 100 comedies, the titles of 50 of which are preserved. He sometimes acted himself. To judge from the imitations of Plautus (*Casina* from the *Κληρονομία*, *Asinaria* from the *Ὀνείρας*, *Rudens* from some other play), he was very skilful in the construction of his plots. Terence also tells us that he introduced into the *Adelphi* (ii, 1) a scene from the *Συναποθήκη*, which had been omitted by Plautus in his

adaption (*Commorantes*) of the same play. The ancients were undecided whether to class him among the writers of the New or Middle Comedy.

DIPHTHERIA, is a specific localized and superficial bacterial infection which is associated with formation of membrane, composed of fibrin and necrotic tissue and with general intoxication. The lesion is normally situated in the upper respiratory tract but occasionally related to previous wounds or ulcers of the skin.

Although primary localizations of the infection in the nose or nasopharynx on the one hand and the larynx on the other are not uncommon, the tonsils and faucial pillars are the site at which the lesion most often appears. A tough, closely adherent membrane which leaves a raw surface when torn away is most characteristic but there are a number of early or mild cases, especially those in the immunized, which present scattered patches of softer membrane more readily detached. These are not easily distinguished from follicular tonsillitis. It is also noteworthy that the severest infections may present lesions in which oedema and swelling are more prominent than membrane formation and so mask it.

Although there is no absolute relationship between the extent of membrane formation and the severity of the infection, it is generally accepted that the spread of membrane over the whole tonsil with progressive involvement of the soft palate, uvula, pharynx and larynx normally indicates a severe case. In rarer instances extension to the oesophagus or downward in the bronchial tree is observed. Swelling of the lymphatic glands of the neck and oedema of the periglottic tissue may be a marked feature and in the worst cases goes on to "bull neck." Nasal discharge and fetor are also common features of the severer cases. The membrane passes through three phases, an early one not often recognized, in which it resembles raw white of egg, a second one in which it suggests the same substance after heat coagulation, and a final one suggesting rubber, with all colour shades from gray to reddish brown. Special sites are the larynx and nose and more rarely the eye, vagina and skin.

General Symptoms—These may be slight or absent in mild cases. In moderate or severer cases there are the usual prodromata of any infection, considerable initial fever of very short duration is the rule, and sore throat is present but is not a commanding symptom. In the severest cases evidences of profound toxæmia are pallor, a soft and irregular pulse, general weakness and marked subjective consciousness of illness. Vomiting, a rapid fall in the pulse and hemorrhagic manifestations are all of grave prognostic significance. Evidences of toxic neuritis appear in a variable percentage of cases and are observed between the sixth day and the sixth or seventh week. In order of frequency and time of appearance paralysis of the palate, the eye, the pharynx and the muscles of the trunk and limbs are observed. The palate lesion is indicated by nasal voice and regurgitation of fluids by the nose, that of the eye muscles by squint, failure of accommodation and, more rarely, ptosis, and the pharyngeal lesion by difficulty in swallowing.

Causes of Death—Death may result in four different ways: a primary massive toxæmia affecting mainly the heart and leading to death within three days, a less profound toxæmia leading to heart failure within the first two weeks, obstruction of breathing caused by membrane formation and oedema of the upper respiratory tract, and late deaths associated with extensive paralytic manifestations which may be directly or indirectly responsible, e.g., diaphragmatic paralysis or inhalation pneumonia, but in which heart involvement probably also plays an important part.

Diagnosis—Although many well-developed cases of diphtheria will be diagnosed without hesitation by any experienced observer, a proportion of early, mild or unusual cases can be certainly diagnosed only by bacteriological investigation. Even with a positive bacteriological result, in such cases there remains the question whether a diphtheria carrier condition coincides with some other infection which is actually responsible for the clinical symptoms. Bacteriological diagnosis is usually made by combining the observation of morphology of mixed cultures on F. Loeffler's inspissated serum medium and the appearance of individual colonies on one

of the blood tellurite agar media. The sugar fermentations of the isolated strains are frequently determined and when by these means the strain is shown to belong to one of the three main types, virulence tests may be restricted to cases of special difficulty—carriers of long standing, wound diphtheria, etc. This is especially so when the gravis and intermedius types are in question.

Ætiology—There was a gap of 57 years between Pierre Bretonneau's classical description (1826) of the disease as a sharply defined infectious condition and E. Kleb's demonstration of the appearance of the bacillus in the superficial layers of the membrane in 1883, followed by F. Loeffler's much more convincing and significant bacteriological investigations.

The causative bacillus described by Loeffler and for long known as the Klebs-Loeffler bacillus, or K L B, and now generally referred to as the *Corynebacterium diphtheriæ*, is a gram positive bacillus, nonmotile and nonsporing with a special affinity for methylene blue which particularly emphasizes the presence of granules showing different staining affinities from the rest of the bacillus, metachromatic granules and irregular swellings of the bacillary body, "clubbing."

The bacillus is extremely pleomorphic. It grows moderately well on the usual media with a basis of meat extract and peptone, but peculiarly well on inspissated serum reinforced with peptone broth and glucose (Loeffler's original medium). It ferments glucose and other sugars without gas formation but not saccharose, although some rare exceptions have been observed.

Three well defined cultural types of the *C. diphtheriæ*, gravis, intermedius and mitis, were first described in Leeds, 1930-34. These are distinguished by the appearance of their colonies especially in primary culture on blood tellurite agar. Gravis is further differentiated from the others by its capacity to ferment starch and glycogen and intermedius by the fact that it never produces hæmolytic. Broadly, gravis and intermedius strains are associated with the severer toxic cases of diphtheria and mitis more often with extensive membrane formation and phenomena of respiratory obstruction. The gravis strain appears to play a special role in epidemic diphtheria and in the diphtheria of the inoculated.

Diphtheria Toxin—The fact that filtrates of culture free from bacteria could kill experimental animals with the systemic lesions of a diphtheria infection was first demonstrated by P. P. E. Roux. From that time production of toxin for immunization of man and of horses was the subject of a vast amount of investigation, and it was only after 1930 that the underlying principles were so far elucidated that the perplexing irregularities in toxin yield from cultures were largely eliminated. The essentials appear to be a suitable peptone as source of nitrogen, combined with fatty acid and carbohydrate, especially maltose, as sources of energy in such proportions as to ensure a slow reversal of reaction from slight acidification to a pH of about 8.6 after several days' incubation in conditions in which there is a large exposure of surface relative to the volume of culture. The importance of the iron content of the medium has also been demonstrated. The Park-Williams 8 strain maintained its place as a constantly highly toxigenic strain and was almost universally used for toxin production on a large scale. The toxin was purified till it is believed to contain little more than 1% of impurity, and such products kill the guinea pig in ratio of 1/1,000,000 g per kilogram of animal body weight. It appears to be a protein free from carbohydrate and phosphorus but containing sulphur.

Treatment—The existence of curative properties in the serums of animals which had recovered from infections was first observed by Emil von Behring in 1890, and the correlation of his work with that of Roux led to the rapid development of antitoxin therapy with the serums of immunized horses. The therapeutic value of such serums was established beyond doubt by the halving of the death rate in the disease in Paris in 1894 (Roux and others) and by the treatment of alternate cases with and without antitoxin over a year in the Blegsdam hospital in Copenhagen by J. Fibiger in 1898.

It was increasingly used thereafter, and emphasis was put on large doses and early treatment. The former were facilitated by new methods of antitoxin purification—partial enzyme digestion

followed by differential heat denaturation in acid solution. It is doubtful, however, whether the use of huge doses of concentrated serums gave results much superior to those obtained in the early days in which smaller amounts of cruder preparations were employed. There are trustworthy records of death in the hypertoxic cases of diphtheria seen so much in Europe after 1925, notwithstanding intensive serum treatment within 24 hours of onset. Estimations of circulating toxin in such cases on admission reveal amounts greater than a lethal dose for man (Wildfuhr, 1947, *Zeit. Innere Medizin Grenz.*, 2, 186).

Tracheotomy.—This operation was much less common after 1927. How far this was the result of the higher age incidence of diphtheria or to changes in the aetiological agent is not certain, both may have played a part.

Epidemiology and Prophylactic Control.—In considering the epidemiology of diphtheria, it is necessary to take into account both the natural fluctuations of the disease and the effect of artificial measures of control which were introduced in modifying these fluctuations. The measures of control are (1) the bacteriological recognition of cases of the disease followed by the search for, and segregation of, carriers of the bacillus, (2) the institution of serum treatment of cases and contacts, and (3) the recognition of persons susceptible to diphtheria by the Schick test and their subsequent immunization by prophylactic inoculations.

That there are marked fluctuations of the severity of diphtheria and of its tendency to epidemic spread both from place to place and over periods of years in the same area is beyond question. The causes underlying these fluctuations in severity and epidemic spread of diphtheria are complex and may include sequences of cold and wet years on the one hand and dry and warm years on the other (Friedrich Wolter), periods of malnutrition following wars and consequent famine or partial famine, the replacement of less formidable by more formidable types of the *C. diphtheriae* consequent on extensive migrations of population in wartime and, finally, fluctuations in mass immunity of the population following epidemic outbreaks.

A comparative study of available mortality and case incidence figures for North America and Europe shows that, notwithstanding a marked fall in diphtheria deaths from the time of the introduction of serum in 1894, diphtheria was still responsible in the 1920s for a considerable morbidity and mortality in North America and most countries of northern and central Europe. This declined steadily in North America to become almost negligible in some of the great cities of Canada and the U.S. following intensive campaigns of prophylactic inoculation. In Europe there was great diversity. In Norway and the Netherlands low levels similar to those experienced in North America were recorded between 1935 and 1939 independently of prophylactic inoculation, whereas the appearance of an unusually severe diphtheria was recorded in central Europe and some of the Irish and English cities, and diphtheria throughout Germany reached very high levels. This culminated in an explosive outbreak of diphtheria in the countries surrounding Germany during World War II which reached its apex between 1943 and 1946, except in Great Britain, where an extensive campaign of immunization appeared to cut it short about 1941. After the close of World War II diphtheria continued to recede gradually

in North America and receded sharply in western Europe but more slowly in Germany and Switzerland, while in Hungary it actually increased.

An outstanding problem is how far the better results in the western hemisphere are attributable to more thorough campaigns of inoculation and how far to a less severe type of diphtheria. It is notable that the type of bacillus described as *C. diphtheriae gravis* is widespread in Europe and rare in North America.

Methods of Prophylactic Inoculation.—The original method of giving toxin-antitoxin mixtures was abandoned because of occasional disasters caused by persistence of toxin after destruction of the antitoxin. This was liable to happen when the mixtures were frozen and the cresol preservative separated in concentrated form. For many years formal treated toxin has been used either as alum-precipitated toxoid (A.P.T.) or as toxoid-antitoxin flocculi which are better tolerated by adolescents and adults. The dosage which has been found most satisfactory is two 1 c.c. injections of A.P.T. at intervals of four to six weeks, provided the A.P.T. contains at least 50 Lf per cubic centimetre. Inoculation should be carried out between the 6th and 18th months of life and followed by a further booster dose before a child goes to school. The incidence of infection among children so treated is greatly diminished and diphtheria deaths are exceedingly rare. Even better results were claimed with prophylactics such as P.T.A.P. prepared from highly refined toxoid absorbed on pure aluminum phosphate. There was also emphasis on the need to immunize earlier in infancy in communities where diphtheria is rare and there is little inherited immunity.

Transmission.—This occurs in several ways: (1) the ejection of infected droplets from the throats of cases or carriers, (2) spread of contamination from infected nasal discharges, probably of first importance, (3) persistence of *C. diphtheriae* in the dust of ward floors which investigations reveal as common, (4) infection of milk or ice cream, to which several well authenticated minor epidemics have been convincingly traced.

Control.—In school and closed institutions this is effected by inoculation or re-inoculation of all not recently immunized, which may be combined with immediate passive protection with antiserum and followed by the detection and isolation of carriers. In the community at large, only prophylactic inoculation has yielded convincing results. It is obvious from the recrudescence of epidemic diphtheria after many years of detection and isolation of carriers that the efficacy of such methods is limited.

DIPLODOCUS, a large amphibious dinosaur found in the Upper Jurassic rocks of the Rocky mountain region, skeletons or replicas are to be seen in many museums. It reached a length of 87 ft., but was relatively slender in build. (See illustration in *DINOSAURIA*.) (A. S. RA)

DIPLOMACY is a word often used vaguely with different meanings. Sometimes it is used to express the whole content of international affairs, sometimes to express the manner in which personal affairs are conducted. Sometimes it is used in a pejorative sense, sometimes it is described as a highly commendable activity. Its proper and main meaning is, however, the manner in which international relations are conducted. Numerous definitions of it exist, but, perhaps, the best is that of the *Oxford English Dictionary*: "Diplomacy is 'the management of international relations by negotiation the method by which these relations are adjusted and managed by ambassadors and envoys, the business or art of the diplomatist.'" This definition seems too limited, for a president, a prime minister or a foreign secretary negotiating in Washington, London or Paris is engaging in diplomacy as much as any ambassador or envoy. It stresses, however, the main point that it is the method not the object of the negotiation that is the subject of diplomacy. But objects may be sought by good diplomacy and vice versa. Still diplomacy is in a sense a substitute for force, it is the means of obtaining the maximum national advantage without the use of violence and, perhaps one might add, with the minimum of friction and resentment. It is also true however, that sometimes it is interspersed with the threat of coercion, and it always depends in some degree on the power, whether military, economic, moral or deriving from association with others, of the state for which the diplomatist is acting. Some writers define it as a science, others as an art. It has indeed characteristics of both, though it is certainly more an art than a science.

The word in the use defined above is comparatively a newcomer. It is derived through the French from the Greek word *διπλωμα* that is, diplōma (literally, a doubling), meaning a folded paper, such as was early used for state papers, charters, etc., and hence a privilege, licence or degree conferred on a person. Thus a "diplomat" was a person so licensed, and in the 18th century this word came to be specially applied to those authorized to negotiate on behalf of the state. Long before this, the word "diplomatic" was used to denote the science of deciphering documents such as the original diplomas, and it is still used in this sense.

HISTORY

Though the word is new, the thing itself has existed since the beginning of civilization—or even earlier. When one group of men wished to come to some arrangement with another group so as to avoid the conflict of arms, they sought to reach an understanding by negotiation. This is the essence of diplomacy. In the early days of human history, when the tribes were small and the distances between them were short, the negotiations were often conducted by the chiefs themselves. As the tribes grew larger and more numerous, and as the distances between them increased, the negotiations were often conducted by specially appointed envoys or ambassadors. These envoys were often men of high rank and were often accompanied by a retinue of attendants. The negotiations were often conducted in a formal manner, and the envoys were often given special privileges and immunities. The system of diplomacy as we know it today, however, is a relatively recent development. It is the result of the growth of the nation-state and of the increasing complexity of international relations. In the 15th century, when the nation-state was first being formed, diplomacy was a simple matter of negotiation between the rulers of different states. As the nation-state grew in power and influence, however, diplomacy became a more complex and formalized system. The growth of the nation-state led to the development of a system of international law, and this in turn led to the development of a system of international relations based on negotiation and diplomacy. Today, diplomacy is an essential part of the life of every nation-state, and it is a profession that is becoming increasingly important in the world of the future.

skilful of Greek statesmen, who cultivated the art of persuasion, and a set of rules for diplomacy began to appear. The Romans took less from the Greeks in this than in some other arts though they used diplomacy effectively both in their relations with the Greeks themselves and in obtaining the control of Egypt. But when the Roman empire was fully established diplomacy was mainly employed to divide and control the barbarians who surrounded it. When the empire split, the western part became a Christian commonwealth owing allegiance to an emperor and to a pope, and though diplomacy was necessary between its warring members and was often conducted by church dignitaries, not only was it sporadic but also, in a sense, there was an appeal to a superior over all participants. The power of these superiors was, however, always very limited, and the papal court itself through the legates contributed a great deal to the development of the diplomatic system.

The eastern empire slowly decayed and, as its power weakened, had to employ negotiation to preserve itself against its attackers, so that it gradually developed a body of professional experts for that purpose who established the reputation of Byzantine diplomacy (see ROMAN EMPIRE, LATER). In the middle ages diplomatists were called by many different names such as legates, nuncios, procurators, agents or ambassadors. In all this development there was no permanent diplomatic machinery even between states which had frequent relations with one another.

The Italians were first to establish permanent missions, in the 15th century. The intense rivalries of the city states, their various combinations and alliances, the growth of their trading connections with the Levant and with northern Europe and the energy intellectual eminence and ambitious spirit of their peoples made them the leaders in the new art of diplomacy. It is usual to attribute to this Italian pre-eminence that characteristic of unscrupulous diplomacy to which the term Machiavellian is given because Niccolò Machiavelli described it in remarkable language in his *Principe* and his *Discorsi sopra la prima decada di Tito Livio*. But in the 16th century the Renaissance rulers of other nationalities, Louis XI of France, for example, were no less unscrupulous than the Italians, though the latter produced more subtle and refined personalities and had distinguished men of letters among their envoys. It cannot be said when the first resident embassy came into existence: the system grew out of the various methods of conducting international relations established during the middle ages among the countries of the Mediterranean area. One cause of delay was the fear that a permanent representative might be corrupted by the ruler to whose court he was accredited. But whatever its origin, it was in the Italian city states that the system came to fruition, Milan and Venice playing the leading part. It was Venice, because of its vast connections in the eastern Mediterranean, threatened by the rising power of the Turk after the fall of Constantinople in 1453, that extended the system into one that became European. Preoccupied with obtaining support for its colonies and for its trade, Venice sent a succession of envoys to Burgundy, since neither the Holy Roman emperor nor the king of France seemed likely to lead the alliance of Christian states which, it was fondly hoped, might arise to resist the infidel. When these efforts failed, Venice used diplomatic methods at Constantinople itself with considerable success. Meanwhile Venice had begun to establish permanent missions in western Europe.

The Development of the Profession—New types of monarchies were then arising as the power of the pope and of the emperor declined and new methods of organizing the central power of the state came into existence. These monarchies naturally began to negotiate with one another in the new way. For some time they regarded it with great suspicion. Henry VII of England, Ferdinand of Spain and Louis XI of France considered foreign agents as little better than spies. But if they were forced to allow rulers of other states to find out much about their own situation, they in their turn obtained much information and important contacts by means of their own agents.

It is also perhaps significant, as has been suggested, that permanent embassies arose at the same time as permanent armies. One could be regarded as the antidote of the other. At any rate in the

first half of the 16th century, in the age of Thomas Wolsey, of Francis I and of Charles V, the system of permanent diplomatic missions became firmly established among the leading European states, and for reasons both of prestige and security smaller states had necessarily to follow their example. Thus arose in nearly all capitals a diplomatic body which came later to be called the diplomatic corps, a number of diplomats each intent on forwarding the interests and defending the honour of the monarch or republic which he represented.

Naturally such men could not be subjected to the ordinary laws of the state where they resided, as is described below, a system of special immunities was gradually elaborated so that they could go about their business without interference. But they had also to establish their names and titles, their method of intercourse, ceremonial procedure and conventional language. The rules that were gradually adopted were part of the system of what was later called international law (*q.v.*) which grew up in the 17th and 18th centuries.

The term "ambassador" (from French *ambassadeur*, the form used by Jean Froissart, *cf.* Low Latin *ambactia*, service) became the designation of the monarch's representative in the 16th century, except the representatives of the pope, who were termed nuncios or legates—though the latter were something more than diplomats. To save expense and for other reasons an inferior and less costly class of agents was instituted, at first called residents or ministers resident, later called envoys. In both classes the word "extraordinary" was added to the title, being at first used to designate special missions but coming gradually, because of disputes as to precedence, to be assumed by all. Later a further class accredited not to the monarch but to his ministers, was used to fill up intervals or when some incident prevented full diplomatic representation, members of this class became known as *chargés d'affaires*. By the end of the 18th century there were four main classes, which were definitely recognized as such in an annex to the treaty of Vienna of June 9 1815; and in a protocol of the congress of Aix la Chapelle (Nov. 21 1818) (1) ambassadors, legates and nuncios, (2) envoys extraordinary and ministers plenipotentiary, (3) ministers resident, and (4) *chargés d'affaires*. (See *AMBASSADOR*.)

The title Excellency (*q.v.*) was first given to an ambassador when Henry IV of France gave it to Louis, duke of Nevers, who was entitled to it as he belonged to the Italian princely house of Gonzaga. The ambassadors of Spain and Venice immediately claimed the same title, and at the congress of Munster, which prepared the peace of Westphalia (*q.v.*), it was given to all ambassadors. It was shared by nuncios and legates but not by lesser ranks. In the course of time it also came to be given, on the continent of Europe, to all those who hold or have held the position of minister in a cabinet, and, in the British Commonwealth to viceroys, to governors general and to some other governors. It has been also claimed that an ambassador has the right at any time to an interview with the monarch to whom he is accredited, but this privilege was never fully established. The language of diplomacy was originally the international language of mediæval Europe, Latin. In the 17th century this was superseded by French, which remained the principal diplomatic language until the end of the 19th. The use of English had been carefully safeguarded, however, and the right to use English in diplomatic communications insisted upon by the government in Westminster, while other governments made analogous reservations. Not until the Paris conference of 1919 was the perfect equality of English with the French language accepted by other governments, largely thanks to the influence of the United States.

By the beginning of the 19th century diplomacy had developed in extent and technique. In some states the foundations of departments of foreign affairs had been established, and the ministers were assisted by professional advisers. Instructions to ambassadors were drafted with competent skill, notably in France, courier services were organized, and ciphers, first used by the Venetians, were employed with imperfect success to guard the secrets of correspondence.

The ambassadors were much preoccupied with the dignity of

their office for in affront was considered as reflecting on the honour of the monarch whom they represented. The precedence was given precedence and in most states was recognized as the *de jure* or *de facto* of the diplomatic corps. But the rivalry of France and Spain, each claiming special precedence, led to many bitter quarrels, and it is said that some doors in London houses were made especially wide so that the two ambassadors could enter the room side by side. Representatives of smaller states had their own special rivalries and court officials everywhere had to be aware of the injury that might be caused to the interests of their own country if these sensibilities were not taken into account. Not until the above mentioned agreements of Vienna and of Aix la Chapelle was precedence by date of appointment accepted by all states; for the classes of diplomats then established. Alphabetical order in the French language was also agreed to in the signature of treaties and similar documents, each state coming first in its own copy. Conventional rules as to the form of correspondence and address had also been established though each court had its own ceremonial practice for the reception and entertainment of diplomatic agents. As relations between states increased practical questions occupied the minds of diplomatists and etiquette was of less importance.

The 19th Century.—Thus the diplomatic profession, while still largely in its higher ranks in the hands of the nobility, became in many countries a debate career. In the 19th century foreign affairs were dealt with in great departments, as other business of the state. By 1815 in France and in Austria prominent officials already managed much of this business. In Great Britain the foreign ministers for a longer period did most of the important work themselves aided only by a few clerks. But in London also by the middle of the century the permanent officials had necessarily to do much more as the dispatches multiplied. First the railroad and then to a much greater extent, the telegraph transformed the tempo of diplomacy, and some of the older statesmen found the change a trying one.

The position of an ambassador also became somewhat different when he could seek instructions from home and receive an answer in a matter of hours instead of days or even weeks. Technical questions especially those of trade, occupied more of the time and energy of diplomats. Commercial treaties had for a long time been negotiated by special envoys working under the general direction of the ambassador and receiving their instructions from ministers of finance or of commerce—in Great Britain from the board of trade. Finally commercial attachés were appointed. There were also military and naval attachés to report on the ever-growing armies and navies.

In addition an attempt had been made in 1815 to set up a permanent international organization of the Great Powers, the European alliance, often called mistakenly the Holy Alliance, the latter name being that of the less practical treaty sponsored by Tsar Alexander I. The alliance broke down in 1823, but in 1830 began the system of ambassadorial conferences—mainly of the Great Powers—which persisted sporadically throughout the century. In 1899 and 1907 two conferences of wider scope met at The Hague to lay down rules for arbitration and revise the rules of war. A number of technical international organizations were also set up with their own conferences and secretariat. Thus the origins of what was later called "diplomacy by conference" were already in existence.

Diplomatic Immunities.—Diplomatists could not be governed by the same laws as the people among whom they dwelt, and from an early date it was recognized that they had special privileges. Hugo Grotius gave his great authority to the theory, already adumbrated, that these immunities as they were called were based on extraterritoriality (*q.v.*) or extraterritoriality, the fiction that the diplomatist's dwelling was part of the territory of his own country and that he carried with him its law. They are, however, really based on practical convenience. Without them, though not necessarily in their most extreme form it would be impossible for the diplomatic agent to perform his functions satisfactorily. Diplomatic agents were thus placed outside the criminal and civil law of the land. They could not be arrested on a criminal charge or sued for debt in a civil court.

During the 16th and 17th centuries these immunities were firmly

established by numerous precedents. There were, indeed, a few exceptions, and even as late as the early 19th century ambassadors at Constantinople might be threatened with imprisonment. But the rules were very generally observed in all civilized communities. Perhaps the one most challenged was exemption from prosecution for refusal to pay debts, which was more than once successfully contested. But the immunities were extended to the diplomatic agent's wife and suite and even to his menial servants, since otherwise his freedom of action would be limited by consideration for those who depended on him and on whom he depended for the exercise of his functions.

This privilege was in many countries, especially in the orient, often abused in earlier centuries, and even in the 19th century it was sometimes a source of profit to the diplomatic agent. Since a diplomatic agent's house is inviolable the right of asylum for political refugees was at one time of importance, especially in Latin America, but it was always regarded with jealousy and not held to be good in the case of ordinary criminals who could be taken by force if not surrendered. A diplomatic agent has also the right of worshiping in his own faith inside his residence, at one time a matter of great importance. He and his suite are exempted from taxation and customs duties. He has naturally also the right of free communication with his own country unless he allows himself to be shut up in a besieged town. On this analogy the diplomatic body in Great Britain was prevented from using cipher dispatches or couriers during the period before the invasion of the European continent in 1944.

In return for these privileges the diplomatic agent had the duty of never creating a breach of the peace or civil disturbance. He was indeed expected to avoid all interference in the internal affairs of the host country. If he failed to do so the only remedy was expulsion. This was the case even when he could be shown to have plotted with others against the sovereign to whom he was accredited (as more than once happened in the 16th, 17th and 18th centuries), though he could be seized so as to be rendered harmless until the expulsion had taken place. In 1915 Constantin Dumba, the Austro-Hungarian ambassador, and Capt. Carl Boy Ed and Capt. Franz von Papen, the German military and naval attaches, were summarily expelled from the United States for attempted sabotage by fomenting strikes and violence in munitions factories, and later a similar fate befell Count von Luxburg, the German minister in Buenos Aires, Arg. The same penalty had often been inflicted for much smaller offenses, some of them little more than a failure in tact or judgment.

It was, however, more usual to ask that the diplomatic agent should be recalled by his own government. Such action should not be taken without sufficient cause, though it has been maintained that it is simply sufficient to declare an agent to be *persona non grata* as justification for desiring his removal. But if this is done unreasonably, reprisals may follow and a rupture of diplomatic relations take place.

THE 20TH CENTURY

During the 19th century diplomacy became a highly organized profession, and its exponents were for the most part chosen for their technical efficiency. In democratic countries the foreign minister was nearly always a politician who might have had no experience whatever of diplomacy, he was also the member of a cabinet or under a president who decided policy, subject to certain legislative control. In the more autocratic countries the foreign minister was often himself a professional diplomatist. The old anarchy still played a notable part in the profession in many countries, and in Great Britain there was an income qualification for the diplomatic service, and its members tended to be chosen exclusively from the upper class. Moreover of the foreign ministers of Great Britain between 1815 and 1914 only two were not either a peer or the son of a peer (George Canning and Sir Edward Grey). The control of parliament was also limited by ignorance of many important facts. "It is in the Cabinet alone that questions of foreign policy are settled," Lord Palmerston told Richard Cobden. "We never consult Parliament until after they are settled." Diplomacy still remained highly secret and, to the man in the

street, mysterious. The treaties which bound the states of Europe together in the period before World War I were nearly all unknown to the peoples whose actions they pledged. Even Great Britain had secret discussions with France which, though they left the former free to determine its own course of action, yet were a moral obligation which could not be disregarded. During the war secret treaties were made which only became known when revealed by the Bolsheviks after the Russian Revolution.

The press it is true, took an increasing interest in foreign affairs. In return the foreign ministers and diplomatists generally took an increasing interest in the press and tried to control it either by bribery or by more subtle methods. Its use became part of the technique of diplomacy. Some journals were controlled by powerful financial and commercial interests, which thus obtained an influence on foreign affairs. Independent papers such as the *Times* (London), the *Frankfurter Zeitung* or the *Neue Freie Presse* exerted a real effect on public opinion and consequently on legislatures and cabinets. Governments had to defend themselves by publishing correspondence showing the manner in which diplomatic transactions had taken place. But it still remained true that many things, and often the most important, were kept secret. It was natural therefore, that there should have arisen during World War I an insistent demand in many countries that secret treaties should be abolished and that much more information should be given to the public about foreign affairs. In addition, two other developments in international affairs began after that war to exercise an important effect on diplomatic methods for the first time in history: a world wide permanent international organization had been set up in the League of Nations, which brought together diplomatists from many different countries, and new technological developments including those which affected communications, made the use of expert knowledge on many different subjects a necessity to the diplomatic profession.

Democratic Control.—In a number of countries the constitution provided machinery through which the legislature exercised some control over the executive in foreign affairs. The most famous and effective was that of the United States, where all treaties had to be sanctioned by a two thirds majority of the senate before they could be ratified, the president also had to obtain the consent of the senate to the higher diplomatic appointments. This system had resulted in the rejection of many treaties, including the most famous of all, the treaty of Versailles, signed by Pres. Woodrow Wilson in 1919.

In some other countries there was provision for the legislature to be consulted before treaties could be ratified. In France, committees of the chambers on foreign affairs were able to obtain secret information from the foreign minister, and the same device was also used in some other states. In Great Britain the executive had the power to ratify treaties, but it was recognized that it could only do so in important cases if parliament had previously indicated approval. British ministers could be questioned in parliament, but there was no formal method by which secret information could be disclosed. Military and naval staffs played an active part in the determination of foreign policy in all countries and the military and naval attaches in contacts between governments. In Great Britain this position had been recognized by the establishment of the committee of imperial defense, which in effect became the war cabinet during World War I.

It was no easy task to devise means by which these processes should be made more democratic. The first of President Wilson's fourteen points laid down that there should be "open covenants of peace openly arrived at, after which there shall be no private international understandings of any kind, but diplomacy shall proceed always frankly and in the public view." This meant that there should be no more secret treaties and not that treaties should be negotiated in public, and it was implemented by a clause in the Covenant of the League of Nations that no treaties should be considered binding unless registered with the secretariat of that body and published. This did, indeed, prevent secret treaties between members of the League of Nations, though military arrangements for mutual defense naturally could not be disclosed. In Great Britain the first Labour government established the rule that no

treaty should be ratified until it had lain on the table of the house of commons for at least 21 days. In other countries similar principles were accepted, though none went so far as the United States, since it was widely held that the control of the senate had done great harm to international co-operation and understanding.

Another step was to make the diplomatic profession more easily accessible to candidates from every class. In Great Britain the income qualification for the diplomatic service was abolished and new methods of appointment and examination introduced. It took, however, some time for such measures to have any great effect and it was often said, both there and in other countries, that the diplomatic profession was out of touch with the classes that had most power in the more democratic society that was growing up. At the same time diplomacy became even more concerned than before with economic and technical questions, and this meant that men of many different types took some part in it. The embassies of the Great Powers in each other's capitals became large and highly organized machines.

Attempts were also made to educate public opinion on the real nature of diplomatic transactions and on the complicated character of the problems with which diplomatists have to deal. Debates in parliament on foreign affairs multiplied, and a larger quantity of diplomatic documents was laid before the legislatures. One example of this was the publication by many countries of the diplomatic correspondence of the period before World War I, in order that the causes of the great catastrophe might be more fully understood. In many countries, also, new institutions for the study of foreign affairs and for the dissemination of information about them were set up, a notable example being the Royal Institute of International Affairs in London. The new international institutions also assisted in the education of public opinion wherever it could follow what took place in them.

A further step was greater co-operation with the press. In all foreign offices press departments were set up and press attachés were stationed at the principal missions abroad. Most of this work was done with the object of getting sufficient attention paid to the policy of the operating country both in its domestic and in the foreign press. But there were also, inevitably, attempts to influence the press to support a particular policy. The cruder forms of journalism, on the other hand, often distorted the information by sensational writing which appealed to national susceptibilities. It was apparent on such questions as that of reparations from the defeated countries after World War I that the governments learned their lessons before the public on which their actions ultimately depended.

As the power of an only partly instructed public opinion over foreign affairs became greater, governments began to use new methods to influence it, not only in their own country but in others. Departments of propaganda were organized which appealed to peoples over the heads of their governments. This practice, first begun by the Soviet government at the end of World War I, was adopted by other authoritarian regimes that appeared elsewhere. The development of radio communication provided them with a new instrument for their purpose. The Italian radio station at Bari, for example, poured out a flood of anti-British propaganda to the Arab countries, and when the National Socialist state had been established in Germany, propaganda, which Hitler himself laid down should be based on lies, was developed into an instrument of aggression. Though this new form of propaganda had great effect in the period between World Wars I and II, it was shown in World War II that a more realistic and truthful presentation of the facts was in the long run more advantageous. After World War II when much radio activity was being employed by both blocs into which the world was divided in the 'cold war' between Communist and anti-Communist states, a similar result was to be expected.

Thus diplomacy had to take place in a new atmosphere in which its professional exponents sometimes found it hard to adjust themselves. The high hopes that a more democratic approach to its problems would ensure a more peaceful world were disappointed. It is true that aggression came from countries where democracy failed. But in the democratic countries there was an inadequate

conception of the true nature of diplomatic transactions, and public opinion was often deceived and misdirected until it was too late to achieve the desired ends.

Diplomacy by Conference—Meanwhile the new international institutions had done much to transform the technique of diplomacy. They also gave the smaller powers a greater opportunity to play an important role in it than they had ever before possessed. The increase in communications and the new technical developments had made new forms of international co-operation necessary, and the process had long been going on. But the discussion of acute international problems in public by men of different nations was a new phenomenon, and still more so the attempt to solve them around the council table in this manner. Of course, there had to be much confidential discussion at Geneva either in secret meetings of the council or among the foreign ministers who came there from many European countries and even from other continents. But there was also much done by public debate in the council and assembly. Opinions were divided as to the effect of this process on the solution of international problems, some insisting that public opinion was thus able to exercise a beneficial influence, others that it made it more difficult for governments to make the necessary concessions and compromises. However that might be, the process certainly depended on free communications between states. Where authoritarian governments controlled the sources of information, the public received only a distorted picture of events at Geneva. The deduction was sometimes made that international institutions could be successful only if their members were truly democratic in the sense of allowing the full expression of different points of view.

The effect on the technique of diplomacy was certainly considerable. Not only had a new language to be learned for the public discussion of controversial problems, but personal contacts multiplied between the foreign ministers themselves and between their principal officials. The use of an international secretariat also transformed the methods of reaching agreement on international problems.

Nevertheless, contacts through the ordinary diplomatic channels still played an important part in the relations between states, and the diplomat had to retain his mastery of the old technique as well as to learn the new methods made necessary by the progress of democracy and of new international institutions. After World War II these institutions increased in number and activity, and a diplomatic struggle took place within them in a manner previously unparalleled. Language was used which in previous periods would have been equivalent to a declaration of war, indeed it was said that such methods were appropriate only to war and could not be given the name of diplomacy. At the same time, all the while, negotiation went on as before, both publicly and secretly, and the art of diplomacy remained of fundamental importance in the relations between states.

The Qualities of a Diplomatist—The essential qualities of a diplomatist have been laid down by many writers, some with considerable experience of the profession, others after studying and analyzing historical records. Some few writers, of whom Machiavelli is the principal representative, have described diplomacy as an attempt to outwit opponents by artifice and treachery, and it is true that much diplomacy has used such means. But the majority of writers have rather tended to stress more virtuous qualities as essential to real success in the profession. Certainly one of the main assets of a successful diplomatist is the confidence of those with whom he negotiates, and this he can obtain only if he takes into account the interests of other countries as well as those of his own and can be trusted to tell the truth, if not always all the truth.

Much negotiation now takes place between groups of states whether in international institutions or in more limited meetings, and a fruitful result can be obtained only by creating the climate of opinion in which agreement is possible. It is then necessary to devise the written instruments in which agreement can be recorded and to perceive the right moment at which to make the maximum effort. Good timing is indeed, an essential factor of diplomacy. It is, of course, also necessary to have debating skill and a complete

knowledge of the facts and for this reason in important negotiations diplomats are generally assisted by a number of experts and advisers. Much diplomacy is therefore teamwork and the influence of the individual diplomatist is consequently reduced. Nevertheless the same qualities of prudence, foresight, energy, courage and regard for others still count as much as they ever did, even if the great decisions on international affairs are made in a very different manner from those of previous generations.

REFERENCE.—Works on international law, books on the foreign policy of states and the history of states are all to be included in the extensive literature of diplomacy. But there are also special treatises for example the standard work in English, Sir Ernest Satow, *Guide to Diplomacy, Practice and Procedure* (London, 1917, 1932). Sir Harold Nicolson *Diplomacy* 2nd ed. (London, Oxford, 1928) the best short account, Julia C. Thompson *The Diplomat* (London, 1928), *Trans. London, 1931* for modern practice, Sir Charles Webster *The Art and Practice of Diplomacy* (London, 1922), Vladimir Potemkin (ed.), *Histoire de la diplomatie*, 3 vol. (Paris, 1920-27) deals mainly with policy but also with diplomatic methods, from the Soviet point of view. For earlier history, see Léon Duguit, *Les Communications de la diplomatie et le droit d'ambassade jusqu'à Grotius*, 3 articles in the *Revue de droit international* xi-xvi (Paris), Garret Malley, "The First Resident Embassies: Medias et Origins of Italian Diplomacy in Speculum xii (Cambridge, Mass., Oct., 1917). L. K. Adair, *The Exteriority of Ambassadors in the Western and Seventeenth Centuries* (London, 1910). J. A. J. Jusserand *L'École des ambassadeurs* new ed. (Paris, 1914). T. G. P. Smith (ed.), *Life and Letters of Sir Henry Welton* 2 vol. (Oxford, 1907). Jean Hotman, *Traité du devoir de l'ambassadeur* (Dusseldorf, 1601, Paris, 1604), Eng. trans. *The Ambassador* (London, 1901). François de Calaneo, *Traité de la manière de négocier avec les souverains* (Paris and Amsterdam, 1716, Eng. trans., London, 1919). Abraham Wicquefort, *L'Ambassadeur et ses fonctions* (Amsterdam, 1710). For the middle years of the 19th century see Charles de Martens *Guide diplomatique*, 5th ed., 2 vol. (Paris, 1866) and P. L. E. Pradier-Fodéré, *Cours de droit diplomatique*, 2 vol. (Paris, 1851). Denis P. Myers, "Notes on the Control of Foreign Relations," *Revue des rapports*, part in, *Organisation Centrale pour une Pax Durable* (The Hague, 1917), surveys the constitutional position in 1914. For the period since 1914 see Sir John Tilley and Stephen Gaisford, *The Foreign Office* (New York, 1931), showing the effect of World War I. H. W. V. Temperley (ed.), *The History of the Peace Conference of Paris*, 6 vol. (Oxford, 1920-24), *Survey of International Affairs*, Royal Institute of International Affairs (Oxford, annual), Lord Havers *Diplomacy by Conference*, *Sixties in Foreign Affairs, 1920-1929* (London, 1926, New York, 1927). (C. K. W.)

DIPLOMACY is the science of the critical study of official as opposed to literary sources of history, that is to say, of charters, acts, treaties, contracts, judicial records, rolls, chartularies, registers and kindred documents. The employment of the word "diploma" as a general term to designate an historical document is of comparatively recent date. It is a Greek word, meaning literally a doubled or folded sheet, and was used by the Romans to denote, first, a passport or licence to travel by the public post and, later, any imperial grant of privileges. It was applied by the humanists of the Renaissance to important deeds and acts of sovereign authority, to privileges granted by kings and by great personages and by degrees its significance became extended to embrace the documents of the middle ages in general. The study of such documents, when Latin was the universal language of scholarship, was called *res diplomatica*, which, when learned books began to be written in the vernacular, was translated into "diplomatic."

History.—The first great text-book, the *De re diplomatica*, issued in 1681 by the learned Benedictine Dom Jean Mabillon, of the abbey of St. Germain des Prés, was called forth by an earlier work by Daniel van Papenbroeck, the editor of the *Acta Sanctorum* of the Bollandists, who, with no great knowledge of archives undertook to criticize the historical value of ancient records and monastic documents and cast wholesale doubt on their authenticity. Mabillon's refutation of Papenbroeck's criticisms was complete and was accepted by Papenbroeck himself. The *De re diplomatica* established the science of secure texts, and, though its immediate result was a flood of controversy between the Benedictines and the Jesuits it has been the foundation of all subsequent works on this subject.

In Spain the Benedictine P. Pérez published in 1658 a series of dissertations following the line of Mabillon's work. In England Madox's *Formularie Anglicanum* (1701) and Hickes's *Insecurum*

septrionialis thesaurus (1705) both endorsed the principles laid down by the learned Frenchman. In Italy Maffei appeared with his *Isoria diplomatica* in 1727, and Muratori, in 1740, introduced dissertations on diplomatic into his great work, the *Antiquitates Italicae*. In Germany, the first diplomatic work of importance was that by Bessel, entitled *Chronicon Gotwicense* and issued in 1732.

France, however, the cradle of the science, has continued to be the home of its development. Mabillon had not taken cognizance of documents later than the 13th century, but a more comprehensive work was compiled by two later Benedictines, Dom Toussaint and Dom Tassin, viz., the *Nouveau Traité de diplomatique*, in six volumes, 1750-55, which embraced more than diplomatic proper and extended to all branches of Latin palaeography. Although the arrangement of this book is faulty, it contains a mass of valuable material, and more modern compilers have made extensive use of it.

As a result of the Revolution, the archives of the middle ages lost in France their juridical and legal value, but this rather tended to enhance their historical importance. The taste for historical literature revived. The Académie des Inscriptions and fusthered it. In 1821 the École des Chartes was founded, and, though at first it did little, it received a further impetus in 1829 by the issue of a royal ordinance re-establishing it. Thenceforth it has been an active centre for the teaching and encouragement of the study of diplomatic throughout the country, and has produced results which other nations may envy. In Germany and Austria there has also been a systematic study of diplomatic archives, more or less with the support of the state, nor has the science been neglected in Italy. In England a late start was made, but much has been done within recent years to make up for lost time. The publications of the Public Record Office and of the department of MSS in the British Museum are now very numerous and are issued more regularly than in former times. The publication and criticism of documents are functions of various learned societies, and there are lectureships in palaeography and diplomatic at several universities.

Classification of Documents.—Documents may be classified under the two main heads of public and private deeds. In the former category are the legislative, administrative, judicial and diplomatic documents emanating from public authority in public form: laws, constitutions, ordinances, privileges, grants and concessions, proclamations, decrees, judicial records, pleas, treaties, in a word, every kind of deed necessary for the orderly government of a civilized state. In early times many of these were comprised under the general term of "letters," *litterae*, and to the large number of them which were issued in open form and addressed to the community the specific title of "letters patent," *litterae patentes*, was given. Those which were issued in closed form under seal on the other hand were known as "close letters," *litterae clausae*.

Under the category of private documents are included not only the deeds of individuals, but also those of corporate bodies representing private interests, such as municipal bodies and monastic foundations. The largest class of documents of this character is composed of conveyances of real property and other title deeds. These are commonly described by the generic name of "charters," and are to be found in thousands, not only in the great public repositories, but also in the archives of municipal and other corporate bodies throughout the country and in the muniment rooms of old families. There are also the records of the manorial courts preserved in countless court-rolls and registers, while many of the documents of the dissolved monasteries represented by collections of charters and chartularies, or registers of charters, have fortunately survived and exist both in public and in private keeping.

The formalities observed by the different chanceries of mediaeval Europe which are to be learned from a study of the documents issued by them, are so varied and often so minute that it is impossible to give a full account of them within the limits of the present article. We can only state some of the results of the investigations of students of diplomatic.

Papal Chancery—First and foremost stands the papal chancery, which has served as a model for all others. Organized in remote times, it adopted for the structure of its letters a number of formulae and rules which became more and more precise from century to century. The apostolic court being organized from the first on the model of the Roman imperial court, the early pontiffs naturally collected their archives, as the emperors had done, into *scrinia* (boxes). Pope Julius I, A.D. 337-353, reorganized the papal archives and Pope Damasus, A.D. 366-384, built a record office at the Lateran. The collection and orderly arrangement of the archives provided material for the establishment of regular diplomatic usages, and the science of formulae naturally followed.

For the study of papal documents four periods have been defined, each being distinguished by some particular development of forms and procedure. The first period is reckoned from the earliest times to the accession of Leo IX, A.D. 1048. For almost the whole of the first eight centuries no original papal documents have survived. But copies are found in canonical works and registers, many of them false, and others probably not transcribed in full or in the original words, but still of use, as showing the growth of formulae. The earliest original document is a fragment of a letter of Adrian I, A.D. 788. From that date there is a series, but documents are rare before the beginning of the 11th century, all of which exist, being written on papyrus. The latest existing papyrus document is dated A.D. 1022, the earliest on vellum A.D. 1005. The nomenclature of papal documents even at an early period is rather wide. In their earliest form they are letters, called in the documents themselves *litterae*, *epistolae*, *pagina*, *scriptum*, sometimes *decretum*. A classification, generally accepted, divides them into (1) Letters or Epistles the ordinary acts of correspondence with persons of all ranks and orders, including constitutions (a later term) or decisions in matters of faith and discipline, and encyclicals giving directions to bishops of the whole church or of individual countries, (2) Decrees, being letters promulgated by the popes of their own motion, (3) Decretals, decisions on points of ecclesiastical administration or discipline, (4) Rescripts (called in the originals *preceptum*, *auctoritas*, *privilegium*), granting requests to petitioners. The comprehensive term "bull" (the name of the leaden papal seal, *bulga*, being transferred to the document) did not come into use until the 13th century.

The second period of papal documents extends from Leo IX to the accession of Innocent III, A.D. 1048-1198. At the beginning of the period formulae tended to take more definite shape and to become fixed, but it was under Urban II, A.D. 1088-99, that the principal formulae became stereotyped. The distinction between documents of lasting and those of transitory value became more exactly defined, the former class being known as greater bulls, *bullae majores* (also called *privilegia*), the latter lesser bulls, *bullae minores*. The introduction of subscriptions of cardinals as witnesses to greater bulls had gradually become a practice. Under Victor II, A.D. 1055-57, the practice became more confirmed, and after the time of Innocent II, A.D. 1130-45, the subscriptions of the three orders were arranged according to rank, those of the cardinal-bishops being placed in the centre under the papal subscription, those of the priests on the left, and those of the deacons on the right.

By degrees the use of the lesser bulls almost entirely superseded that of the greater bulls, which became exceptional in the 13th century and almost ceased after the migration to Avignon in 1309. In modern times the greater bulls occasionally reappear for very solemn acts, as *bullae consistoriales*, executed in the consistory.

The third period of papal documents extends from Innocent III to Eugenius IV, A.D. 1198-1431. The pontificate of Innocent III was a most important epoch in the history of the development of the papal chancery. Formulae became more exactly fixed, definitions more precise, the observation of rules and precedents more constant. The staff of the chancery was reorganized. The existing series of registers of papal documents was then commenced. The growing use of lesser bulls for the business of the papal court led to a further development in the 13th century.

They were now divided into two classes, *tituli* and *mandamenta*. The former conferred favours, promulgated precepts, judgments, decisions, etc., the latter comprised ordinances, commissions, etc., and were executive documents.

In the fourth period, extending from 1431 to the present time, the *tituli* and *mandamenta* have continued to be the ordinary documents in use, but certain other kinds have also arisen. Briefs (*brevia*), or apostolic letters, concerning the personal affairs of the Pope or the administration of the temporal dominion, or conceding indulgences, came into general use in the 13th century in the pontificate of Eugenius IV. They are written in the italic hand on thin white vellum, and the name of the Pope with his style as *papa* is written at the head of the sheet, e.g., *Eugenius papa iii*. They are closed and sealed with the Seal of the Fisher man, *sub anulo Piscatoris*. Briefs have almost superseded the *mandamenta*.

Merovingian Chancery—Of the chancery of the Merovingian line of kings of France as many as 90 authentic diplomas are known, and of these 37 are originals, the earliest being of the year 625. The most ancient examples were written on papyrus, vellum superseding that material towards the end of the 7th century. All these diplomas are technically letters and were authenticated by the king's subscription, that of the *referendarius* (the official charged with the custody of the royal seal), the impression of the seal, and exceptionally by subscriptions of prelates and great personages. The royal subscription was usually autograph, but, if the sovereign were too young or too illiterate to write, a monogram was traced by the scribe. They are of two classes: (1) Precepts, conferring gifts, favours, immunities, and confirmations, entitled in the documents themselves *praeceptum*, *praeceptio*, *auctoritas*, some drawn up in full form, with preamble and ample final clauses, others less precise and formal, (2) Judgments (*iudicia*), which required no preamble or final clauses as they were records of the sovereign's judicial decisions, they were subscribed by the referendary and were sealed with the royal seal.

Carolingian Chancery—The diplomas of the early Carolingians differed but little from those of their predecessors. The royal subscription was in form of a sign-manual or mark, but Charlemagne elaborated this into a monogram of the letters of his name built up on a cross. Most of his diplomas were authenticated by the subscription of the chancellor and impression of the seal. A novelty in the form of dating was also introduced, two words, *datum* (for time) and *actum* (for place), being then employed. The character of the writing of the diplomas, founded on the Roman cursive hand, which had become very intricate under the Merovingians, improved under their successors, yet the reform which was introduced into the literary script hardly affected the cursive writing of diplomatic until the latter part of Charlemagne's reign. The archaic style was particularly maintained in judgments, which were issued by the private chancery of the palace, a department more conservative in its methods than the imperial chancery. It was in the reign of Louis Debonair, A.D. 814-840, that the Carolingian diploma took its final shape. A variation then appears in the monogram, that monarch's sign-manual being built up, not on a cross as previously, but on the letter H, the initial of his name Hludovicus, and serving as the pattern for successive monarchs of the name of Louis.

In the Carolingian chancery the staff was exclusively ecclesiastical, at its head was the chancellor, whose title it traced back to the *cancellarius*, or petty officer under the Roman Empire, stationed at the bar or lattice (*cancelli*) of the basilica or other law court and serving as usher. As keeper of the royal archives his subscription was indispensable for royal acts. The diplomas were drawn up by the notaries, an important body, upon whom devolved the duty of maintaining the formulae and traditions of the office. It has been observed that in the 9th century the documents were drawn carefully, but that in the 10th century there was a great degeneration in this respect. Under the early Capetian kings there was great confusion and want of uniformity in their diplomas, and it was not until the reign of Louis VI, A.D. 1108, that the formulae were again reduced to rules. The acts of

the imperial chancery of Germany followed the patterns of the Carolingian diplomas, with little variation down to the reign of Frederick Barbarossa, AD 1152-1190.

England—For the study of diplomatic in English material exists in two distinct series of documents, those of the Anglo Saxon period and those subsequent to the Norman Conquest. The Anglo Saxon kings appear to have borrowed, partially, the style of their diplomas from the chanceries of their Frankish neighbours, introducing at the same time modifications which give those documents a particular character marking their nationality. In some of the earlier examples the lines of the foreign style are followed more or less closely, but very soon a simpler model was adopted which lasted in general construction down to the time of the Norman Conquest. The royal charters were usually drawn up in Latin, sometimes in Anglo-Saxon, and began with a preamble or exordium, in the early times of a simple character, but later drawn out not infrequently to great length in involved and bombastic periods. Then immediately followed the disposing or granting clause, often accompanied with a few words explaining the motive, such as for the good of the soul of the grantor, and the text was closed with final clauses of varying extent, protecting the deed against infringement, etc.

In early examples the dating clause gave the day and month (often according to the Roman calendar) and the year of the indiction, but the year of the Incarnation was also immediately adopted, and later the regnal year also. The subscriptions of the king and of the personages witnessing the deed, each preceded by a cross, but all written by the hand of the scribe, usually closed the charter. A peculiarity was the introduction in many instances, either in the body of the charter or in a separate paragraph at the end, of the boundaries of the land granted, written in the native tongue. The sovereigns of the United Kingdom, usually styled themselves *rex*. But from the time of Aethelstan, AD 852-890, they also assumed fantastic titles in the text of their charters, such as *rex et primicerius, rex et rector, gubernator et rector, monarchus et princeps* the Greek *basileus* and *basileus induratus*. At the same time the name of Albin was also frequently used for Britain.

A large number of documents of the Anglo Saxon period, dating from the 7th century, has survived, both original and copies entered in chartularies. Of distinct documents there are nearly two hundred, but a large proportion of these must be set aside as copies (both contemporary and later) or as spurious deeds.

Although there is evidence of the use of seals by certain of the Mercian kings, the method of authentication of diplomat by seal impression was practically unknown to the Anglo-Saxon sovereigns, save only to Edward the Confessor, who, copying the custom which obtained upon the Continent, adopted the use of a great seal.

Immediately after the Norman Conquest of England the old tradition of the Anglo-Saxons disappeared. The Conqueror brought with him the practice of the Roman chancery, which naturally followed the Capetian model, and his diplomas of English origin differed only from those of Normandy by the addition of his new title, *rex Anglorum*, in the superscription. But even from the first there was a tendency to simplicity in the new English chancery, not improbably suggested by the brief formalities of Anglo Saxon charters, and, side by side with the more formal royal diplomas, others of shorter form and less ceremony were issued, which by the reign of Henry II had quite superseded the more solemn documents. By the reign of John these simpler forms had taken final shape, and from this time the acts of the kings of England have been classified under three heads, viz. (1) Charters, generally of the pattern described above, (2) letters patent, in which the address is general, the king himself is his own witness, and the great seal is appended, (3) close letters, administrative documents conveying orders, the king witnessing.

The style of the English kings down to John was, few exceptions, *Rex Anglorum*; thenceforward, *Rex Anglie*. Henry II added the feudal titles, *dux Normannorum et Aquitanorum et*

comes Andegavorum, which Henry III curtailed to *dux Aquitanie*. John added the title *dominus Hibernie*, Edward III, on claiming the crown of France, styled himself *rex Anglie et Francie*, this title being borne by successive kings down to the year 1801, and Henry VIII, in 1521, assumed the title of *fides defensor*. The formula *Dei gratia* does not consistently accompany the royal title until the reign of Henry II, who adopted it in 1173.

The forms adopted in the royal chanceries were imitated in the composition of private deeds, which in all countries form the mass of material for historical and diplomatic research. The student of English diplomatic will soon remark how readily the private charters, especially conveyances of real property, fall into classes, and how stereotyped the phraseology and formulae of each class become, only modified from time to time by particular acts of legislation. The brevity of the early conveyances was maintained with only moderate growth through the 12th, 13th and 14th centuries. The different kinds of deeds must be learned by the student from the text-books, but a particular form of document which was especially in favour in England should be mentioned. This was the chirograph (Gr *χρῆφ*, a hand, *γράφειν*, to write), which is found even in the Anglo Saxon period, and which got its name from the word *chirographum*, *cirographum* or *cyrographum* being written in large letters at the head of the deed. At first the word was written, presumably, at the head of each of the two authentic copies which the two parties to a transaction would require. Then it became the habit to use the word as a tally, the two copies of the deed being written on one sheet, head to head, with the word between them, which was then cut through longitudinally in a straight, or more commonly waved or indented line, each of the two copies thus having half of the word at the head. Any other word, or a series of letters, might thus be employed for the same purpose. The chirograph was the precursor of the modern indenture, the commonest form of English deeds, though no longer a tally. In other countries, the notarial instrument has performed the functions which the chirograph and indenture have discharged for us.

DIPLOPIA, seeing a single object as double, occurs when ever one of the two eyes leaves the correct position of fixation, i.e., when one eye can not focus on an object simultaneously with the other eye. An object clearly seen by the normal eye gives rise to an image in the deviated eye to one side of the macula and is referred by the mind to a position different from that which it really occupies. Thus, there seem to be two objects, one clearly seen with the normal eye and one indistinctly seen by the deviated eye. Causes of deviation of one eye are (1) disturbances in the motor apparatus of the eye, (2) tumour or abscess in the orbit, (3) limitation of motion of the eyeball from without. Paralysis, or weakness of one or more of the eye muscles, is by far the commonest cause of ocular deviation, and it is in those cases which come on suddenly that diplopia is a striking feature. It occurs frequently in alcoholic intoxication and in encephalitis lethargica and less often in poisoning by lead or carbon monoxide and in certain acute infectious such as diphtheria and polio-encephalitis.

DIPNOI, see FISHES, LUNG-FISH

DIPNOENUS and SCYLLIS, early Greek sculptors, who worked together, and are said to have been pupils of Daedalus. Pliny assigns to them the date 580 B.C., and says that they worked at Sicily, which city from their time onward became one of the great schools of sculpture. They also made statues for Cleonae and Argos. They worked in wood, ebony and ivory and apparently also in marble. It is curious that no inscription bearing their names has come to light.

DIPPER, or **WATER-OUSEL**, a bird about the size of a thrush, squatly built and of an active disposition. The dipper (*Cinclus cinclus*) haunts the rocky streams of Europe and North Asia. The dipper, belonging to a small family of its own, the Cinclidae, feeds upon small fresh water molluscs and crustacea, which it captures under the water, walking along the bottom of the stream and aiding its progress with its wings. It can also swim on the surface of the water, despite the fact that its feet are not webbed. The upper parts are dark, the throat and breast white, and the belly has a chestnut band. Its ringing song may be heard even in winter. The white eggs, four to seven in number, are laid in a cup shaped nest of grass, lined with dead leaves and completely encased and domed with moss, except for a small hole to admit the bird. There are five species in the family, found in the northern hemisphere (see OUSEL).

In North America, this genus is represented by *C. mexicanus* in the mountains of the west. The American bird lacks the white throat of the European form, which it otherwise resembles closely. The Costa Rican dipper (*C. ardesiacus*) of the highlands of Costa Rica and Chiriqui is similar, with the general colour a lighter gray.

DIPSACACEAE, a family of dicotyledonous plants, the best-known member of which is the teasel (*q.v.*). The family includes 10 genera and 150 species. The scabiouses (*Scabiosa knautia*) also belong to this family.

DIPSOMANIA, a term formerly applied to the attacks of delirium (*q.v.*) caused by alcoholic poisoning. It is sometimes loosely used as equivalent to the condition of incurable inebriates but strictly should be confined to the pathological and insatiable desire for alcohol, sometimes occurring in paroxysms.

DIPTERA, the term used in zoological classification for the two winged or true flies which form one of the largest orders of insects. Their chief character is expressed in the name of the order (*Gr* *ἴς* double, and *πτερά* wing) and, with certain aberrant exceptions, flies possess a single pair of membranous wings corresponding with the anterior pair in other winged insects. hind wings are absent and are represented by a pair of small knobbed organs termed halteres or balancers. The mouth parts are always adapted for sucking and sometimes for piercing also, and the various organs combined form a proboscis. Flies undergo complete metamorphosis and their larvae are always devoid of legs and most often have a much reduced head, the pupae are either

free or enclosed in a hardened shell or puparium. The foregoing definition embraces about 75,000 described species, and, of this number, about 3,500 kinds inhabit the British Isles, and new species are continually being found in almost all countries. As a rule, flies are of small or moderate size. Some species are even minute, measuring one millimetre long, while some Australian robber flies exceed three inches in wing expanse with a body length of one and three quarters inches. The majority of flies are diurnal and frequent flowers for their nectar or haunt decaying organic matter of diverse kinds, very many kinds never visit flowers but are found on foliage, tree trunks, fallen logs, in grass, on the ground or on mud where they seek their food. Some are crepuscular (active only at dawn or dusk or on very dark days). The primitive blood-sucking species, such as mosquitoes and sand flies, are mostly crepuscular or nocturnal. Many species are predaceous upon smaller insects, mites and small worms. A relatively small number have acquired the blood-sucking habit, confined chiefly to the females, and a small number of these are of great importance because of their ability to transmit various diseases to man and other animals. The pathogenic organisms of malaria, yellow fever, elephantiasis, onchocerciasis and other diseases are transmitted from animal to man, and from man to man, through the agency of biting flies, and can not be contracted in any other way.

Diptera are generally of sombre coloration, but many are conspicuously banded or spotted with black and yellow, many are metallic green, blue or violaceous, while others are densely hairy and coloured like bees. Many of them resemble wasps and act like them, when captured, they buzz loudly by vibrating the wings and some even bend the tip of the abdomen against the skin as though to sting. Some of those that resemble small bees are parasitic on them, while most of the ones that live in the nests of ants and termites are usually greatly modified, at least in the females. The sexes are usually closely alike but dimorphism is not uncommon. In some flies with long antennae (mosquitoes, etc.) these organs are much more densely plumose in the males, and in this sex the compound eyes often approach each other more closely than in the females, and very frequently they are contiguous.

General Structure.—The head is generally a somewhat spherical capsule, with much of its surface often occupied by the compound eyes, which are usually very large and composed of

hundreds of facets, rarely small and having very few facets and absent in only a few cases, usually three ocelli are situated near the top of the head between the eyes, but these are frequently absent. The antennae, generally rising close to the middle of the front of the head are of diverse form (fig. 1) and are of great importance in classification. The mouth parts (fig. 2) are highly modified for sucking. Mandibles are only present in those flies that feed by piercing and are lancet like, the maxillae in such flies are of similar form but usually they are reduced, partly fused with the head and chiefly represented by their palpi. The labium is membranous and forms the greater part of the proboscis, and

its apex is expanded to form two sucking lobes or labella. The thorax is fused into a single mass chiefly formed by the large mesothorax and the legs have five jointed tarsi. The membranous wings (fig. 4) frequently have the venation reduced and there are but few cross veins, in certain parasitic and other flies wings are absent. In the family the abdomen often has its terminal segments tubular and retractile forming an ovipositor. The tracheae are frequently expanded to form large air sacs, while the digestive

segments, sometimes with terminal style or with dorsal or terminal arista (fig. 1), the distinction between style and arista is one of thickness, but when dorsal it is always termed arista. Pupa free, often mobile, splitting down the back of the anterior part for the emergence of the adult.

This suborder is subdivided into two series, the Nematocera and Brachycera, these are further subdivided by some authors.

Series Nematocera—Mostly slender flies with elongate antennae of seven or more segments, maxillary palpi with four or five segments. Wings with median cells usually absent. Larvae with an evident head, pupae free.

The Nematocera include 20 families, the most important are the following:

The Tipulidae are commonly called crane flies, or "daddy long legs," and are recognized by the long fragile legs, long wings with many veins, and the presence of a V shaped suture on the back of the thorax. The winter crane flies (Trichoceridae), false crane flies (Ptychopteriidae) and primitive crane flies (Tanyderidae) have the V shaped suture and are frequently included in the Tipulidae. The amazing, practically wingless genus *Chirona* (of Europe and America) is found crawling actively about on snow and quickly becomes inactive if held in the hand or taken into a warm room. The larvae of most species are pale cream coloured or grayish, usually quite soft, and are aquatic or semiaquatic and numerous in swamps and marshes, they inhabit both fresh and brackish water. Those that feed on the roots of grasses and other plants have a heavier covering and are known as "leatherjackets" (qv). The crane flies occur in all land areas of the world, several thousand species having been described. The smallest is about two millimetres, the largest, almost two inches in length.

The Culicidae (figs. 3, 4, *Anopheles*) are known as gnats and mosquitoes (qv), they are slender and delicate, with long legs, the posterior pair being held up by the mosquito when it is at rest. The body and wing veins are partly or wholly clothed with scales of various colours and shapes, in most species those on the wings are spindle shaped or lanceolate, in others they may be broader than long and toothed at the tip, sometimes inflated, or of any intermediate form, there may be only one type of scale on the body or several, there are also bristles and hairs, the former being of the greatest importance in classification, it is the scales which give the colour patterns to mosquitoes and some of them are the most gorgeously coloured of all insects. The mouth parts are stylet like and used, in the females, for sucking blood or sap, the males do not bite. The larvae and pupae are aquatic and are very active, they come to the surface to breathe. *Anopheles* larvae are surface feeders, turning their heads 180° to bring the mouth uppermost. Many larvae have been fully described and the dangerous ones are well known. By 1946 more than 1,700 kinds had been described of which only 29 occurred in Great Britain. The disease carrying species mostly belong to the genera *Anopheles*, *Culex* and *Aedes*. (See ENTOMOLOGY Medical Entomology).

The Simuliidae are called black flies, buffalo gnats and turkey gnats and are easily recognized by their thick antennae and broad delicate wings, the anterior veins heavy, the others very fine. In the males, the eyes broadly touch each other, the two sexes usually differ markedly, the males being much brighter and often with metallic hairs on the thorax. Despite the rather short proboscis the females are vicious biters, but some kinds do not bite man. The larvae and pupae are aquatic, living in running water, the larvae with a pair of mouth fans for securing food and living in a tubular net, pupation takes place in a cocoon in the net, when the adult is ready to emerge, the pupa rises to the surface, the fly emerges and flies away. In 1946 more than 300 kinds were known at least 6 of which carry diseases. (See BLACK FLY).

The Chironomidae, or midges, are small, delicate flies with moderately long, slender legs, venation delicate, the front veins stronger, antennae of the males plumose. The larvae are aquatic or semiaquatic and have been dredged from a depth of more than 1,000 ft from the bottom of Lake Superior, many are red and are called bloodworms. The adults of many kinds are frequently mistaken for mosquitoes; since the mouth parts are short and not

FIG. 2—HEAD AND MOUTH PARTS OF A FLY ALLIED TO THE HOUSEFLY

system usually has a special food reservoir opening into it by a narrow duct. In many flies the ganglia of the ventral chain are fused into a single mass and in some cases, the female reproductive organs are adapted to retain the larvae for a variable period after developing from the eggs.

Classification—The classification of flies is of a very technical character and is somewhat simplified in the following arrangement. Wing venation and the structure of the antennae are the chief criteria for the separation of the major groups and families, but every structure—often very obscure ones—is employed at one time or another in the separation of genera and species. There are three main suborders which embrace most of the families, these are further subdivided. Only the more important families are included below.

SUBORDER ORTHORRHAPHA

Flies in which the head lacks a frontal suture, antennae composed of few to many segments, when composed of four or fewer

FROM THE JOURNAL OF HYGIENE BY COURTESY OF DR. G. H. F. NUTTALL F.R.S.

FIG. 3—HEAD AND MOUTH PARTS OF AN ANOPHELES MOSQUITO SHOWING PIERCING AND SUCKING APPARATUS

adapted for biting they are harmless

The Ceratopogonidae, or biting midges, differ from the chironomids in that the wings are held flat over the back when at rest instead of roof-like, and the femora are sometimes swollen. All are very small, the biting ones usually about two millimetres long, the predaceous ones seldom more than five millimetres. The antennae are long and plumose, the wing venation is typical and the wings are frequently short haired over most of the surface, often resulting in distinct spots. At least half the species are predaceous, others suck the blood of other insects, a few attack warm blooded animals. The life histories are varied, some are aquatic, others live in mud, decaying vegetation and tree holes, others in the tide zone of sandy beaches. The family is small but nearly 50 species occur in Great Britain. (See SANDFLY FEVER)

The Psychodidae, or moth flies, are easily recognized because they are very hairy and quite small, and the wings are bent at a sharp angle near the base and are held roof like over the body

The wings are usually pointed, the veins and margins haired rarely with scales, there are two forked veins three in *Phlebotomus*, two in front of the middle of the wing. The larvae live in decaying vegetable matter, dung and water and possess both open spiracles and tracheal gills. Species of *Phlebotomus* (incorrectly *Phlebotomus*) suck blood and transmit a number of diseases to man—*Verruga peruviana*, Carrion's disease or Oroya fever in the western Andes, pappataci or three day fever, kala-azar or Dum dum fever, and oriental sore in the old world. The adults are mostly nocturnal, including all *Phlebotomus*, but may be found during the day on tree trunks and the undersides of leaves. They walk with a jerky motion, none are more than five millimetres long. *Psychoda* is sometimes a problem in sewage disposal areas and sometimes breeds in washbasin and bathtub drains. There are no *Phlebotomus* in Great Britain, and only four or five in the United States, they are essentially tropical. Other genera are widely distributed. (See ENTOMOLOGY Medical Entomology)

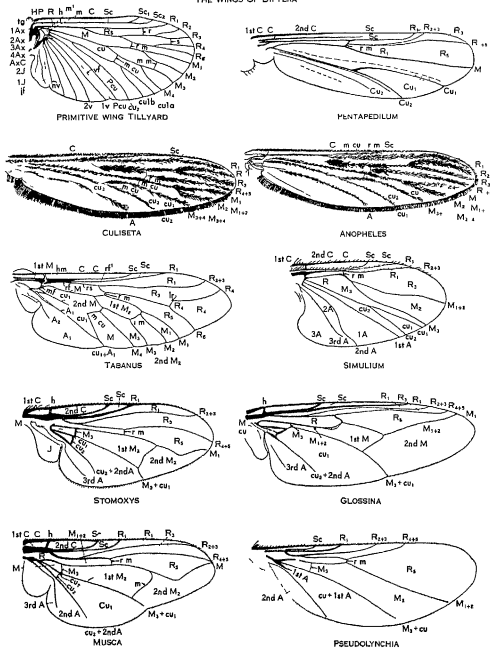

The Cecidomyiidae, or gall midges, are minute flies with very few veins in the wings, which are usually covered with tiny hairs, the antennae are head like and adorned with arclets of hairs, and circumfila—long, filamentous organs arranged in varying patterns and designs and usually attached in several places—are present in most genera. The larvae are often orange in colour, with a minute head, they have a "breast bone" behind the mouth. They make galls of many types and live in the axils of leaves and in flowers, many are serious pests, the best known of which are the Hessian fly (*q.v.*) and the chrysanthemum midge. A few are predaceous on plant lice. (See GALL MIDGE)

The Mycetophilidae, or fungus gnats, are moderately small to small, slender flies in which the coxae are elongated and the eyes widely separated, antennae with 12 to 17 segments, the basal 2 large, the others cylindrical, flattened or petiolate, venation simple, at most 2 cross veins present. The larvae generally feed on fungus and the adults are found in moist places, a very few larvae are luminous and predaceous

The Sciaridae, or dark-winged fungus gnats, differ from the Mycetophilidae in having the eyes closely approach each other above the antennae, most of them have smoky wings and are dark in colour, a few being rusty reddish, veins weak except in front, only one vein branched. The larvae feed on fungus and are sometimes injurious to mushrooms. (See FUNGUS GNAT)

Other families belonging to the Nematocera are the Anisopoda, Blephariceridae, or net winged midges, with their remarkable aquatic larvae, the Deuterophlebeidae, their larvae and pupae equally curious, the Thaumaleidae, with larvae similar to the chironomids, the Bibionidae or, in North America, March flies, and the

THE WINGS OF DIPTERA

FIG 4—WINGS OF DIPTERA, THE LETTERINGS REPRESENT TERMS USED TO DESIGNATE VEINS AND CELLS

Scatopsidae, or minute black scavengers, which feed on decaying vegetation and are often carried into houses in the soil of potted plants

Series Brachycera—Mostly stoutly built flies, the antennae usually with three segments, which may or may not bear a terminal style or dorsal arista, sometimes with four to six segments, rarely more (in some Stratiomyidae and the Rhacidae), maxillary palpi with one or two segments. Wing venation variable.

BY COURTESY OF THE U. S. DEPARTMENT OF AGRICULTURE
FIG. 5.—THE LIFE HISTORY OF THE ROSE MIDGE (*DASYNEURA RHODODAPHNÆ*), A NATIVE OF THE UNITED STATES

the veins usually strong. Larvae generally with greatly reduced retractile head (fig. 8); pupae free, or enclosed in the larval skin and called puparium.

This large suborder is further divided by some authorities from 17 to 30 families are recognized, the most important being mentioned below.

The Stratiomyidae, or soldier flies, are typically more or less flattened, blackish, with white, yellow or green markings; many are metallic blue and green, abdomen often slender and sub-cylindrical; scutellum often with two or more spines. Antennae variable, the third segment usually annulate, long or short, often with terminal or dorsal arista, sometimes as many as ten freely articulated segments. Wing venation is typical—a small cell beyond the middle of the wing toward the front from which three or four usually weak veins arise. The larvae are aquatic or live in mud, decaying vegetation, under bark or on decaying fruit, etc., at least some are predaceous, a few live in brackish water.

There were more than 1,200 described species by 1946. Their chief value lies in their pollination of flowers.

The Tabanidae, commonly called horseflies, deer flies, clegs or greenheads, have more or less broad, somewhat flattened heads, piercing mouth parts and, in life, brightly coloured eyes. The third antennal segment is always annulate, sometimes long, but often short and angulate above, near the base. The eyes of the males are contiguous. The costal vein is continued completely around the wing, the squamae are large. The larvae are predaceous and aquatic or live in mud. The eggs are laid in masses on foliage or twigs over water or mud. More than 2,500 species were known in 1946, mostly belonging to the genus *Tabanus*. All suck blood and many are pests. Some are believed to feed chiefly on birds. Several species of *Chrysops* (deer flies) transmit disease among animals and to man, and some of the clegs (*Haematopota*) carry animal diseases. The females of the American *Gomops chrysochroma* incubate their eggs.

The Rhagionidae, or snipe flies, generally have a tapering body and moderately long legs. Third antennal segment usually with a terminal style or arista, in *Symphoromyia* and *Atherix*—both blood sucking—it is kidney shaped, the arista dorsal. Adults and larvae are predaceous, the former frequenting foliage and tree trunks, the larvae living in fresh water, under bark, in dung, etc. The larvae of *Vermileo* and related genera build funnels in dust in which to trap their prey, the adults are long and slender, with long legs.

The Mydidae, or Midas flies, are all large and have the veins arranged so that they end before the tip of the wing, antenna with four segments, the fourth long, usually without a short style. The larvae live in decaying wood.

The Asilidae, assassin or robber flies, are extremely varied in size, shape, and habits, all are predaceous. They are recognized by having the head concave above, when viewed from in front, and by their wing venation. The eyes usually have an area of enlarged facets, and the ocelli are situated on a tubercle. The antennae have three, very rarely four segments, the third segment with or without a terminal style or arista. The legs are usually spiny, the claws long. The larvae are spiny and occur in a variety of habitats, none are known to be aquatic, some bore in dead trees. (See ROBBER FLY.)

The Bombyliidae, or bee flies (fig. 7), are usually clothed with dense hair, which may be mostly tomentose, but some are almost bare. The colours are the result of the hair, which rubs off very easily, many of them have scales on the body and a few have them on the wings. The mouth parts are usually long, antennae with three segments, and usually short, apical style composed of one or two segments. The adults suck nectar and fly during the hottest part of the day, they often rest on hot soil or warm foliage, and most of them hover.

The larvae are parasitic or predaceous. Of the more than 2,000 species known in 1946, only 9 occur in Great Britain, the largest numbers occur in the tropics. (See BEE FLY.)

The Nemesiidae, or tangle-veined flies, have the veins arranged so that they form several to many extra cells in the wings, and most of them are quite hairy. The adults hover and produce a loud buzzing sound. The larvae, at least of the species of *Hirmoneta*, are parasitic or predaceous upon the larvae of root-feeding beetles.

The Cyrtidae, or small-headed flies, are remarkable not only for

their small, spherical heads but also because they are parasitic on spiders. The eggs of at least some species are broadcast on the soil, the larva develops in the abdomen of the spider. Antennae usually short and with terminal style, proboscis very short or very long, eyes often densely hairy. Although consisting of only about 200 species, the family is cosmopolitan.

FROM ERIG. COLLEGE ENTOMOLOGIST (BY PERMISSION OF THE MACMILLAN CO., PUBLISHERS)
FIG 8—LIFE STAGES OF HIPPELATES PUSIO. AN EYE GNAT OR FRUIT FLY EGGS, LARVA, PUPA AND ADULT

The Empididae, or dance flies, are small, robust or slender, with moderately long legs, antennae with three, rarely two, segments and usually with terminal style or dorsal arista. Adults and larvae are predaceous upon smaller insects and animals, some larvae are aquatic but most live in damp places, such as moss, decaying vegetation, mud and under bark of trees. Many of them visit flowers. The males of some capture prey which is used as a lure for the females, some blow bubbles for the same purpose. The species of *Hilara* spin silken threads which are used to entrap small prey. The length ranges from one-fifth to almost one-half inch. More than 1,600 species were known by 1946, from all parts of the world.

The Dolichopodidae or Dolichopodidae, the long-headed or long legged flies, are generally metallic green, the eyes are much higher than wide, or at least oval, rarely round, antennae three-segmented, with dorsal or apical arista, thorax with bristles, wings with only one large closed cell. The larvae mostly live in mud and humus, some under bark, a few in the stems of plants. The adults are predaceous upon smaller insects, mites and worms and are of great importance, they occur on mud, foliage and tree trunks. Their appendages are often beautifully ornamented and many indulge in nuptial displays. Many kinds run over water consistently. *Dolichopus* is the largest genus of the northern hemisphere, *Condylostylus* replaces it in the tropics, larvae of some species of *Medeterus* destroy bark beetle larvae. More than 2,000 species were known by 1946, the smallest 1 mm, the largest 8 mm long.

SUBORDER CYCLORRHAPHA

Head usually with a frontal suture, with a small plate or lunule (fig 2) above it, antennae usually with dorsal arista, but sometimes with a short apical style (fig 1 B-E). Larvae with minute retractile head, pupae enclosed in the hardened larval skin or puparium (fig 8), which ruptures by means of a circular fracture.

In these flies a kind of bladder (the ptilinum) is protruded through the frontal suture in order to force open the puparium, thus allowing the insect to emerge, the bladder is then withdrawn into the head.

Series Aschiza.—Frontal suture rudimentary or absent, frontal lunule present. Eight families belong here, the most important ones being as follows:

The Phoridae, very small flies, the third antennal segment usually round, the arista usually apical, head and thorax with bristles, wings with strong veins only in front, three or four weak oblique ones behind. Wings very frequently absent in females.

The larvae are found in a variety of habitats, living in fungus and decaying vegetation, on spider eggs and in the nests of termites, ants and bees. More than 1,000 species were described by 1946, all are very small.

The family Brachidae contains a single species, *Brachia coeca*, which originated in Europe and occurs in many parts of the world. It lacks wings and halteres and is known as the bee louse, it is often injurious to weakened hives of bees.

The Platypodidae, or flat-footed flies, have the hind tarsi broadened and flattened on one side, the arista is apical, the larvae live in fungi. The males and females are usually dissimilar in colour.

The Pipunculidae, or big-headed flies, have a large, spherical head, the face and front are extremely narrow, the third antennal segment usually produced downward into a point, the arista dorsal. They are parasitic on bugs, particularly those belonging to the families Cixiellidae and Fulgoridae, at least 12 species attack the beet leaf hopper in North America.

The Syrphidae, commonly called hover flies, flower flies, etc., are the most important of the Aschiza, containing, by 1946, more than 3,000 known species of very diverse habit and form. They are distinguished by having a spurious vein, running between the third and fourth veins and crossing the anterior cross vein (fig 9). The arista is usually dorsal, bare or plumose, third antennal segment variable, rarely with a terminal style, form usually broad, but often very slender. Most of them bear some resemblance to bees or wasps. The larvae are varied in form and habit, many are predaceous upon aphids, etc., others are aquatic or are scavengers, while others live in the nests of bees, wasps, ants and termites. A few are injurious (See HOVER FLY).

Series Schizophora.—The Muscoidea.—Flies having the antennae short, composed of three segments, arista dorsal, rarely a terminal style, frontal suture present.

The Acalypterae.—Squamae or calypteres usually narrow, transverse suture of the mesonotum usually complete, thorax usually with bristles.

This group, a subdivision of the Muscoidea, contains about 40 families of chiefly small flies, some of which are of great economic importance. There is no good dividing line between them and the Calypterae, but the apical cell of the wing is usually fully open and there is no dorsal suture on the second antennal segment, the arista is dorsal, seldom apical. The most important families are included below.

The Conopidae, or thick-headed flies, have the anal cell closed near the margin of the wing, an apical style or dorsal arista present. The adults frequent flowers, they are parasitic on bees and wasps, laying their eggs on them during flight. *Stylogaster*, the female with a very long ovipositor, is associated with ants, but its exact status is not known. More than 500 species had been described by 1946.

The Pyrgotidae resemble the Outidae but lack ocelli, they are crepuscular or nocturnal and are parasitic on the larvae of June beetles.

The Outidae, or pictured-wing flies, are also known as Ortalidae and Platystomatidae. Almost all have the wings banded or spotted with brown, gray or yellowish, they like bright sunlight, where they crawl about on foliage or tree trunks and wave their wings. Most are believed to be scavengers, but the species of *Tritoxa* attack onion bulbs.

The Trupaneidae, or fruit flies, also have pictured wings and wave them in the same way as the Outidae, they differ in having the subcostal or medastinal vein evanescent at the apex or curved forward at a near-right angle, and in other minute details. The adults are found on flowers, fruits and foliage, the larval habits are varied, some make galls, others feed on seeds, mine in plants and bore in fruits. The family is cosmopolitan, more than 1,000 species were known in 1946 (See FRUIT FLY).

The Protophidae is a very small family of black flies. They are

FIG 9—WING OF A SYRPHID, SHOWING SPURIOUS VEIN (A)

scavengers but the larvae of *Prophila cases* feed on cheese and preserved meats. They are able to jump an inch or more, the larva grasps the edge of a ridge on the posterior of the body with its mouth hooks and lets go suddenly, causing it to leap into the air.

The Drosophilidae, or small fruit flies, usually have the arista loosely plumose, with more rays above than below. They are used in the study of heredity (see DROSOPHILA, GENETICS) and are attracted to ripe fruit and fermenting substances.

BY COURTESY OF THE U. S. DEPARTMENT OF AGRICULTURE
FIG. 10.—TACHINID FLY (*EXORISTA LARVARUM*) MALE AND HEAD IN PROFILE

The Agromyzidae, or leaf miners, are small, usually black flies, sometimes marked with yellow, rarely mostly yellowish. The larvae make characteristic winding mines in the leaves of plants, several kinds are rather serious pests of flowers and garden crops. The Chloropidae, or fruit flies, are small and usually mostly black. There is no anal cell, and the third antennal segment is usually more or less rounded, the arista dorsal. Several species are injurious to cereals, others carry disease (See TSETSE FLY).

The Ephyrididae, or shore flies, also lack the anal cell and the arista may be plumose, pectinate (with rays on upper surface only) or bare. They are found near water. The larvae of some are aquatic, others live in mud in stems of aquatic or semiaquatic plants or in flowing sap, some are pests in rice fields. The larvae of *Psiloa petrolei* live in crude petroleum in California, the breathing tube projects above the oil.

The Cryptochaetidae are mostly shining black, they are distinguished from related flies by the absence of an arista, the larvae live on scale insects, in America, *Cryptochaetum scervae*, imported from Australia is an effective parasite of the cottony cushion scale, living within its body, pupation occurs in the host. The flies are rather sluggish. Only about a dozen species were known in 1946.

The Chamaemyiidae are small flies of sombre coloration, usually thickly ashy pollinose. The larvae of *Leuops* somewhat resemble those of the aphid feeding syrphids, but the posterior end is transverse and bears a short appendage at each side, giving them a somewhat triangular outline, they feed on aphids, often hiding in the axils of leaves during the day.

The Psilidae have a peculiar weakened line running across the basal third of the wing; the species of *Loxocera* have long, thin antennae. *Psila rosae* attacks carrots and other umbellifera, on carrots, its tunnels look rust-like and it is known as the carrot rust fly, it occurs in Europe and North America, where, at times, it causes serious damage.

The Calyptridae.—The second antennal segment has a dorsal suture extending practically its whole length, the lower lobe of the squamae is large (except in some Muscidae), the thorax is conspicuously bristled.

This group contains an extremely large number of species of economic importance, they attack man and domestic animals,

carry disease and destroy crops, but the damage they cause is more than offset by their control of other insects. The distinctions between the families are of a minor sort, and the number of recognized families varies with different authors, those generally recognized are discussed below.

The Muscidae (including Anthomyiidae and Scatophagidae) lack bristles on the hypopleura, the third and fourth longitudinal veins are usually parallel, the fourth sometimes curved strongly forward as in *Musca*, the lower lobe of the squamae is narrow (Scatophagidae and most Anthomyiidae), large in the Muscidae, abdomen usually without conspicuous bristles. The adults occur everywhere, are of varied form but are generally robust. The habits of the larvae are variable, most live in decaying vegetation and dung, some are leaf miners or feed upon the roots of plants and sprouting grain, others are semiaquatic, living in mud, wet humus and moss. The larvae are generally similar in appearance, but a few, like *Fannia*, bear fleshy appendages and spines (See BEET LEAF MINER, HOUSEFLY, ONION MAGGOT).

The Glossinidae, or tsetse flies, are distinguished from all other flies by the presence of long, plumose rays on the upper surface of the arista, the proboscis is long and swollen at the base, palpi very long, apical cell of the wing strongly narrowed at apex. The family is found only in Africa (See TSETSE FLY).

The Gasterophilidae are the true botflies, living in horses and related animals. The fourth wing vein is evanescent apically, there are no hypopleural bristles and the lower lobe of the squamae is narrow, the exact position of the family is in doubt, some authors placing it in the Acalyptidae. The eggs are laid on the animal, in varying places, according to the species concerned. The mouth parts are very greatly reduced in this and the following two families (See BOTFLY).

The Cuterebridae, or robust botflies, are confined to the new world and are parasites of rodents, monkeys and large quadrupeds and sometimes man. They have generally very robust forms and are strong fliers, the squamae are large, and hypopleural bristles are present, the postscutellum is not developed. The posterior breathing spiracles of the larvae are situated in a depression which may be closed when the insect is away from the surface. The family, by the two last mentioned characters, shows relationship to the Metopidae (See BOTFLY).

The Oestridae, or botflies, gadflies, warble flies, etc., are usually robust and hairy, the postscutellum is well developed, hypopleural bristles are present and the squamae are large. The posterior spiracles are not situated in a depression. They are parasites of cattle, sheep, deer, etc. They are apparently related to the Tachinidae (See BOTFLY).

The Metopidae, or flesh flies, bluebottles, blowflies, etc., are also called Sarcophagidae, Calliphoridae and Stephanostomatidae. Some authors divide them into a number of families, basing their decision upon the value of certain characters. The arista is bare, pectinate or plumose, hypopleural bristles are present, squamae large, postscutellum not present, thorax always with dorsal bristles, the abdomen usually with bristles, legs strong and bearing bristles. The larvae are varied in habit, most of them feed on decaying animal matter but many are parasitic on snails, caterpillars, grasshoppers, etc., some live in the nests of termites, others in the nests of bees and wasps. Some are of medical importance. The posterior spiracles are situated in a conspicuous cavity which may be closed in liquid media. The family is a very large one, and difficult taxonomically, the males are easily distinguished from each other by the structure of the genitalia, but the females of many can not be distinguished with certainty (See BLUEBOTTLE, FLESH FLY).

The Tachinidae, or tachinids, are separated from the related groups by the presence of a postscutellum, a strong convexity at the base of the scutellum on the undersurface. They are most variable in form and habits, the thorax is bristled, the abdomen usually so, hypopleural bristles are present, the wing venation varies but the apical cell is usually strongly narrowed or closed, arista bare or plumose, antennae variable in size and shape. The larvae are variable, the posterior spiracles flush with the body surface or produced. All are parasitic upon other insects. Many

kinds have been transported from one country to another to help control both imported and native pests. The family is a large one, with scores of new forms described each year. (See TACHINID FLY)

SUBORDER PUPIPARA

Generally flattened, leathery flies, the coxae widely separated, the legs attached toward the sides, wings present or absent, living on birds and mammals, mature maggots are produced by the females.

The Hippoboscidae are mostly bird parasites and sometimes occur in such numbers that they greatly weaken or kill their host. Some live on deer and disperse with their wings as soon as they locate a host, others live on camels. The sheep tick or ked is always wingless and is found wherever sheep are raised, it pupates in the wool, others usually pupate in soil. The adults are of a hard leathery texture and flattened, they are sometimes attracted to the feathers on millinery.

The Streblidae, or bat flies, are also flattened, usually of a yellowish colour and usually with wings, but these are sometimes reduced in size. They are parasitic on bats and often occur in enormous numbers in bat caves.

The Nycteribidae, or spider like bat flies, are only slightly flattened, and the head folds back into a groove on the front of the thorax, they are wingless and usually brown in colour. This and the preceding family are mostly tropical, and both families are quite small.

REPRODUCTION AND DEVELOPMENT

The eggs of flies are of diverse forms and are usually laid in large numbers, thus, a single housefly may deposit more than 2,000 eggs during her life, in masses of 75-150. Many other flies, particularly those that are aquatic or live on decaying matter, also deposit eggs in loose masses or in rows, in *Culex* mosquitoes they are laid in compact rows forming rafts which float on the surface of water. Other flies deposit eggs singly wherever there is sufficient food to nourish the larvae, some scatter hundreds over foliage to be eaten by caterpillars. Most parasitic species lay their eggs on or in other insects, in which they develop, the eggs of certain nematode-like flies are laid in cracks in fence posts or crevices in trees, and the larvae are carried on the wind and eventually seek out white grubs in the soil. Paedogenesis (reproduction in larval state) occurs in *Myiastor*, the larva hatches from the egg and, when partly grown, many larvae develop within it, they bore their way out, destroying their maggot mother, and develop to maturity. Many kinds of flies give birth to living young, the eggs hatch in the body and maggots are deposited on suitable food, this occurs chiefly where the larvae feed on quickly decaying substances such as meat and excrement, in some cases the females may deposit both maggots and eggs. A further development occurs in certain Muscidae of the American tropics, the maggots are deposited at various stages of development, often being half grown, the final development of this nature is found in the tsetse flies and in the pupipara, the maggots are nourished by special cells in the mother's body until they reach maturity, they are deposited at rather long intervals and pupation takes place almost at once.

In most of the common flies there may be several generations a year, the number depending upon the length of the season and temperature, most flies, however, have but one generation a year, and some species require two or three years for development. The egg stage is usually of short duration, from a few hours to a few weeks. The larvae may mature in a few days.

Dipterous larvae are always without legs and many of them are awl-shaped and without a distinct head, in the Nematocera the head is distinct and often conspicuous, as in the mosquitoes. They usually bear an anterior and posterior pair of spiracles, but the latter only may be present. Because of their legless condition, most fly larvae pass a concealed life in the tissues of plants, burrowing in soil or decaying refuse and dung, in the bodies of other animals or in water. When full grown, the larvae transform to the pupal stage, sometimes casting off the larval skin, at other

times the change takes place within the skin, which adheres firmly to the pupa within and is called a puparium, very few build weak cocoons, but many construct cells in the soil. The winter is spent by most flies as larvae or pupae, but some carry over as eggs and some hibernate as adults.

One of the most remarkable life cycles is that of *Psilopa petrolei*, whose larvae inhabit crude petroleum pools in California, some larvae occur in the sea, one kind living in a round ball composed of grains of sand loosely held together by silk, others exist in the hot water of thermal springs. They exhibit an extremely wide range of food preference, probably the majority of their larvae feed upon decaying organic matter. A few families are exclusively plant feeders, but the numbers that are predaceous or parasitic are quite large. There are many structural adaptations to fit them to their mode of life. Most of the parasitic forms have only a single pair of spiracles situated at the caudal end, these either bore a hole through their host's skin or keep open the hole through which they entered and extrude the spiracles from it in order to breathe, some tachinid larvae work their spiracles into the tracheae and obtain air contained therein. Some of the botflies have two forms, the young migratory larvae obtaining their oxygen from the blood of the host until they take up their position under the skin, at which time they bore through and breathe the free air. Mosquito larvae have a similar disposition of the spiracles, projecting the siphon through the surface film of water when breathing, in their pupae the spiracles are situated on the thorax. The larvae of black flies build nets enabling them to live in fast-flowing water, while those of the blepharicercids have series of suckers beneath enabling them to cling to stones, the pupae of these rise to the surface, the adult emerges almost immediately and flies away.

Geographical Distribution.—It may be said briefly that all the important families of flies are very widely distributed but certain of the smaller groups are more restricted in their range. As a rule the largest and most striking members occur in the tropics where some of the most exaggerated developments of form are also found. Generally, however, the members of a given family have a very constant facies, whether they come from the tropics or from temperate regions. The housefly is practically cosmopolitan and is found wherever man has established himself, many other flies such as *Lucia* (greenbottles), *Calliphora* (blowflies) and *Stomoxys* (stable fly) have also become very widely distributed through human agencies, while some of the curious bat parasites (*Nycteribidae*) have a wide distribution dependent upon that of their hosts. On the other hand, the tsetse flies (*Glossina*) are confined to Africa south of the Sahara and the extreme south western tip of Arabia, and the small family *Acanthomeridae* belongs to tropical America and the West Indies. Flies are also met with in very isolated situations. The curious wingless crane fly, *Chionea*, is found in Europe and North America on the surface of snow, while other wingless or semi-wingless Diptera are found on the shores of Kerguelen and other far distant ocean islands.

Geological Distribution.—Diptera is one of the latest orders of insects to appear in geological time and is not met with until the Upper Lias of Europe, where certain Nematocera occur. There appears to be no certain evidence of the existence of the higher families until the Tertiary period. In Baltic amber and in the beds at Florissant, Colo., numerous fossil flies occur.

Economic Importance.—No order of insects exceeds the Diptera in economic importance. A large number of flies in their larval stages are destructive to cultivated plants. Among the most important of these is the fruit fly (*Oscinella frit*) of Europe and North America, which is destructive to growing oats, while the closely allied gout fly (*Chlorops taeniosus*) produces swollen deformations of the ear bearing shoots of barley. Leatherjackets, or larvae of certain crane flies, cause much damage to the roots of cereals and other crops, while the cabbage maggot (*Hyalemya brassicae*) and the onion fly (*Hyalemya antiqua*) entail losses to growers of those vegetables. The Hessian fly (*Mayetiola destructor*) is also a severe pest of cereals, both in Europe and North America. Mention must also be made of the Mediterranean fruit

fly (*Ceratitis capitata*) which attacks almost all kinds of succulent fruit in many tropical and warm regions, including south Europe.

There are other flies whose larvae are injurious to man and domestic animals, and the afflictions induced by their presence are included under the general term of *myiasis*. Included in this category are the Oestridae, especially the warble flies (*Hypoderma*) of Europe and North America, which cause immense losses through perforating the hides of cattle, the larvae of botflies (*Gasterophilus*) are parasites that attach themselves to the alimentary canal of horses and mules. The related sheep botfly (*Oestrus ovis*) troubles sheep, its larvae burrowing in the cranial sinuses. The screw-worm, or larva of *Chrysomya americana* occurs from the United States to Patagonia and infests sores and wounds in animals and even the nasal cavities of man. The sheep maggot flies of Australia and other countries include several species which cause immense losses on sheep farms, their larvae often puncture the skin, causing horrible afflictions, accompanied by bacterial infection of the parts concerned.

There are also numerous flies of blood-sucking habits, whose larvae are not directly injurious. Certain kinds are irritating pests of man and domestic animals, while others of similar habits convey the pathogenic organisms of certain virulent diseases from one animal, or human being, to another. Thus, many species of *Anopheles* mosquitoes are the direct carriers of malaria parasites from man to man. Yellow fever is contracted only when the mosquito *Aedes aegypti* (formerly known as *Stegomyia fasciata*) sucks the blood of man after having previously fed upon an infected person. Another mosquito, *Culex fatigans*, is a carrier of the filaria worm which induces the disfiguring disease of elephantiasis, while the tsetse fly (*Glossina*) is a carrier of the pathogenic organisms (trypanosomes) of sleeping sickness in man and of nagana in domestic animals. The minute moth flies (fam. Psychodidae) include the blood-sucking genus *Phlebotomus*, the members of which are small enough to pass through the meshes of mosquito curtains. Sand fever or papillata fever of southern Europe, North Africa, etc., is transmitted from man to man by a member of this genus. Mention must also be made of the horseflies (fam. Tabanidae), a species of which (*Tabanus stratus*) has been shown to transmit the pathogenic organism of surra among horses and other animals in the Orient.

The housefly (*Musca domestica*), although innocent of blood-sucking habits, is a dangerous carrier of the germs of typhoid, infantile diarrhoea and other diseases. Being attracted to excrementous matter, often containing disease germs, the insect's mouth parts and body thus become contaminated and its faeces include ingested bacilli. Flies infected in this way readily contaminate food which consequently becomes a source of infection to human beings.

The economic importance of Diptera is not confined to their injurious activities, on the other hand, there are many species which are valuable auxiliaries to man. The majority of the predaceous and parasitic forms are beneficial, many larvae of the hover flies (fam. Syrphidae), for example, are important agents in reducing the excess multiplication of plant lice, while the parasitic larvae of the Tachinidae destroy vast numbers of other insects. The role of the latter flies as natural controlling agents has led to their practical utilization in several parts of the world. Thus, the sugar cane borer beetle (*Rhagoctenia obsoleta*) in the Hawaiian Islands is so successfully paralyzed by the tachinid *Cremastus sphenophorus*, introduced to those islands from West Guinea, that it is largely under control. Other Tachinidae have been introduced from Europe and Japan into North America to assist in the control of the gypsy moth and other pests, and conspicuous success has attended the importation of the fly *Phycophora crenata* from Malaysia into Fiji, where it is parasitizing the caterpillars of the coconut moth.

Bibliography.—Although literature on flies is voluminous, there are few comprehensive works of a general nature. The partly completed work, edited by Dr. Erwin Lindner, *Die Insekten der Palaearktischen Region* (Stuttgart, 1926 et seq.) is most thorough, also the uncompleted series *Fauna de France, Diptera* (Paris, 1926 et seq.) For British flies see W. J. Wiegman, "A Preliminary List of British Diptera," *Trans. Nat. Hist. Soc. Northumberland*, vol. 2 (Durham and Newcastle, 1906), also F. W. Edwards, H. Oldroyd, and J. Smart, *British Blood-sucking Flies* (London, 1929). Two volumes by G. H. Verrill, *British Flies*, deal with the Syrphidae and other families, the *Diptera Denica*, in English, by W. J. Lundbeck, is most valuable but covers only certain families, the *Handbook der Palaearktischen Diptera* (Budapest, 1902-05) gives references to species known to that time, the *Catalogue Diptéromorphe* (Budapest, 1902-10) covers world species of all but the Muscidae. For the American species, J. M. Aldrich, *Catalogue of North American Diptera* (Smithsonian Misc. Coll., 46, 1905) is the latest available. *The Families and Genera of North American*

Diptera by C. H. Curran contains keys to genera from Panamá north, including the West Indies, and is useful for other parts of the world, covering all but a few families. *The Fauna of British India, Diptera* (London, 1912 et seq.) deals with many families of Indian flies.

Among the works on special subjects, the following will be found most useful: J. Smart, *Insects of Medical Importance* (London, 1943), C. G. Hewitt, *The House Fly* (1914), R. Newstead, A. M. Evans and W. H. Potts, *Guide to the Study of Tsetse Flies* (London, 1934), F. W. Edwards, "British Non-biting Midges, Chironomidae," *Trans. Entomological Soc. London* (1929), deals thoroughly with this family. Two volumes entitled *Flies and Disease*, by E. Hinde and G. S. Graham-Smith, respectively, may be mentioned, references dealing with flies and disease will be found under the article *Entomology*, and various textbooks on medical entomology should be consulted. Other references dealing with specific subjects will be found under *Mosquito*, *Tachinid Fly*, etc. Among the few books of a popular character are L. C. Muhl, *Natural History of Aquatic Insects* (1902) and J. H. Fabre, *The Life of the Fly* (English trans. from *Souvenirs entomologiques*) (1913). See also A. D. Imms, *Recent Advances in Entomology* (1931). (C. H. Cn., A. D. I.)

DIPTERAL, the term applied to temples that have a double range of columns in the peristyle, as in the temple of Diana at Ephesus.

DIPTEROCARPACEAE, an important family of Palaeotropical trees, the fruits of most genera characteristically two- to five-winged, so as to give them a spiral motion in falling. All of the species are important timber trees, and many of them yield valuable resins. The timber of various Philippine representatives of the genus *Shorea* was extensively imported into the United States under the trade name Philippine mahogany. Twenty genera are usually recognized, with about 400 known species. The family is a characteristic one of the rich primary forests of India and Ceylon, but more especially the eastern peninsula of Asia and the Malay archipelago, there are two somewhat aberrant genera in Africa. The large genera are *Dipterocarpus*, 70 species, *Ausporia*, 20 species, *Hopsea*, 60 species, *Shorea*, 100 species, and *Vatica*, 50 species. *Sal (q v)* is an important timber tree in India (*Shorea robusta*).

For a consideration of the genus see E. Glig, "Dipterocarpaceae," in Engler and Prantl, *Die Natürlichen Pflanzenfamilien*, vol. 21, pp. 237-269, figs. 108-118 (1925). (E. D. M.)

DIPTYCH, (1) Two writing tablets hinged or strung together, used in the Roman empire for letters and documents, especially (made of bronze) for the discharge of time-expired soldiers, also (made of wood or ivory, sometimes of gold or silver, and containing the sender's name and portrait) for a token of a consul's, praetor's or aedile's entrance into office, which he issued to his friends and the public generally (Gr. διπτυχον, two folding).

(2) In the early Christian Church the names of eminent members and benefactors, living or dead, were recorded on diptychs and read aloud from the ambo or from the altar, thereby securing the prayers of the church, especially, in each church, were the names of those who had been its bishops recorded. The reading of these names during the canon of the mass gave rise to the term *canonization*.

The diptych formed the germ of the elaborate system of festal-ogues, martyrologues and calendars which developed in the church. It went by various names in the early church—mystical tablets, anniversary books, ecclesiastical matriculation registers or books of the living. According to the names inscribed a diptych might be a *diptycha episcoporum*, *diptycha martiriorum* or *diptycha vivorum*.

The richly ornamented outsides of consular diptychs sometimes found their way into church treasures, where they were eventually used as covers for copies of the Gospels, or for liturgical prayers, and their tradition was continued in the use of the diptych or triptych form for works of Christian devotional art. (See *IVORY CARVING*). (R. A. S. M.)

DIR, an independent state in the North-West Frontier Province of India, lying to the northeast of Swat. It commands the greater part of the route between Chitral and the Peshawar frontier. The trouble between the khan of Dir and Umra Khan of Jandol were factors that led up to the Chitral campaign of 1895. During that expedition the khan made an agreement with the British government to keep the road to Chitral open in return for a subsidy. Including the Bashkars, an aboriginal tribe allied to

the Torwals and Garhuis, who inhabit Panjkora Kohistan, the population is estimated at about 100,000.

DIRAC, PAUL ADRIEN MAURICE (1902—), British mathematical physicist in the field of atomic structure, was born in Bristol, Eng. He started as an engineering student at Bristol university, but soon shifted to physics and received his Ph.D. from Cambridge university. His pioneer work in the quantum mechanics of the atom won him the Nobel prize (jointly with Erwin Schrodinger) in 1933, at the age of 31. He was awarded the royal medal of the Royal society in 1939. In 1925, when the true quantum mechanics was first being developed by Werner Heisenberg, Louis Victor de Broglie and Schrodinger, he independently developed an equivalent mathematical form, which involved essentially a noncommutative algebra for calculating atomic properties. In his book *The Principles of Quantum Mechanics*, Dirac developed the so-called transformation theory of quantum mechanics which furnished a machinery for calculating the statistical distribution of certain variables when others are specified. He was codiscoverer of the Fermi-Dirac statistics and pioneered in developing the quantum theory of radiation. In his *Quantum Theory of the Electron* he replaced the conventional single second-order Schrodinger wave equation by four simultaneous first order equations. When these equations are solved, various properties of the electron, such as its spin and anomalous magnetic moment, make their appearance in an almost miraculous fashion. For a while, a rather mystifying property of the solutions of these equations was the existence of states of negative energy, which at first did not seem to correspond to physical reality, and hence had to be excluded arbitrarily. However, in a later paper, Dirac suggested that a deficiency of an electron in one of these states would be equivalent to a positively charged particle, of transient life because the state might later become occupied. This concept was confirmed in Carl David Anderson's discovery of the positron (J. H. V.).

DIRCE, in Greek legend, daughter of Helios the sun god, the second wife of Lycus, king of Thebes. After her death (see ANTIOPE) her body was cast into a spring near Thebes afterward called by her name.

DIRECT ACTION In a limited sense, the phrase is used to describe the methods of trade unionism as opposed to parliamentary action for the purpose of obtaining demands of labour for better working and living conditions. In its wider meaning, it refers to the use of trade union action not only for immediate economic and political ends but also for the overthrow of capitalism and the establishment of a socialist order. In this wider sense, direct action is an attempt to reconcile the Marxian idea of class struggle and the anarchist (Proudhonian and Bakuninist) opposition to the state in general and to parliamentary government in particular with the trade union idea that labour can improve its economic and social status only through the power of its professional organizations. For such larger purposes, direct action calls for the use of various forms of the strike (in one or several trades or industries), of the general strike, sabotage, the boycott, the trade-union label and of antiparliamentary and antimilitarist activities.

The idea of direct action was developed in France between 1900 and 1904 by the leaders of the French Confederation of Labour (CGT) and by a group of allied intellectuals of whom the best known was Georges Sorel. Between 1910 and 1914 the idea was taken up by the British labour movement. The most powerful method of direct action. Considering the object for which they have been used in different countries, general

strikes may be divided into four classes: industrial general strikes, general strikes against war, political general strikes, and revolutionary or social general strikes.

Direct Action for Industrial Ends—Some general strikes for industrial ends were not inspired by theories of direct action but were the result of the forms of labour organization and of the methods of wage determination prevalent in the country. Such have been particularly the actual (1909) or threatened general strikes in Sweden. On the other hand, the large strikes conducted by the Industrial Workers of the World in the US in the textile, lumber and other industries during 1911-14 were inspired by the idea of direct action.

Direct Action Against War—The French syndicalists during the decade before World War I were passionately opposed to war, devoted much of their time to antimilitarist and antiwar propaganda and claimed a war could be prevented by a general strike called at the same time by workers of all the countries involved. After 1910, as war began to seem possible in Europe, French and British socialists, among whom the most active were Edouard Vaillant in France and James Keir Hardie in England, urged the socialist international (the so-called second international) to adopt a resolution in favour of a general strike in case of war. The question was debated at great length at the international socialist congresses between 1910 and 1914, but did not receive support from the German Social Democratic party, strongest and largest socialist organization in Europe. The German socialists argued that adoption of such a resolution would make them an illegal party in Germany, and that a general strike under conditions of war would be tantamount to social revolution. No general strike, in fact, was called in any country to prevent the outbreak of World War I. After 1919, the idea of direct action against war gained support for a while. From 1937 to 1939 the majority of organized workers in western Europe and in the US favoured armed opposition to Hitlerism and fascism.

Limited Political Direct Action—Even before the development of the theory of direct action, general strikes were used to force governments to grant limited political and economic concessions. In 1893, a general strike secured universal suffrage in Belgium. In 1902, the Swedish trade unions called a three day general strike to destroy a reactionary government franchise bill, which was withdrawn. In fact, these successful strikes and the general strikes in France during 1902-05 (for the closing of the private employment bureaus, to secure state technical education and for the eight-hour day) which were wholly or partly effective, aroused much enthusiasm in labour circles for the general strike and strengthened the faith in its possibilities as a method both of social reform and of revolution.

During the turbulent years after World War I, general strikes were resorted to in a number of countries for various ends, and with various degrees of success. The general strike in Seattle, Wash., in 1919 failed because the workers, after gaining the upper hand in the city, had no clear program and were defeated by the aroused middle classes and the use of the police force. On the other hand, the Kapp Putsch in Germany in 1920, by which a group of monarchist officers overthrew the republican government, was expeditiously ended by a general strike called by the German trade unions with the assent of the deposed republican government. The British general strike of 1926 was organized in support of the British miners and because of deep resentment against the behaviour of the Tory government but was called off by the trade union leaders after a few days on the realization that it might lead to a decisive struggle of revolutionary scope.

The failure of the British general strike and of others which took place between 1919 and 1926 dampened the enthusiasm for the idea. Besides, the divisions and schisms in the labour movements of Europe during the following decade, the restrictions on the right to strike imposed in many countries and the rise of fascism and nazism made general strikes for limited political ends practically impossible. Only in some Latin American countries was it resorted to as a means of speeding a dictator out of power or of forcing constitutional changes.

An interesting use of the general strike during World War II

was made by the workers of Copenhagen in 1943 which forced the occupying German authorities to relax some of their impositions and evictions. However the most significant development was the resurgence of the political general strike in Europe after World War II. Thus, the Belgian trade unions staged a general strike early in 1945 to force the government, which returned from exile, to give greater recognition to the demands of the more radical elements of the "resistance." A strike threat later in the year helped to prevent the return of King Leopold to Belgium. General strikes in North Italy in 1945 were effective in forcing changes in political and economic administration. General strikes for a few hours or a day occurred in Italy and France during 1946 to demonstrate the solidarity of organized left wing labour against antisocialist and anticommunist groups.

Revolutionary Direct Action—The syndicalists who developed the theory of direct action were primarily interested in its social-revolutionary aspects. The general strike, in this theory, was important as the method by which capitalism would be overthrown and socialism ushered in. Such a social or revolutionary general strike, it was claimed, might be peaceful since the workers by "folding their arms" and stopping all productive work, would force the employing class and the government to capitulate. Just when such a social general strike would or could take place in any country could not be foreseen, but it was the function of the trade unions to hasten the day by sharpening industrial and political conflicts.

A social general strike as conceived by the syndicalists was never called in western Europe or elsewhere, and it is now realized that the idea itself, in the words of Georges Sorel, is largely a "social myth." Under modern social economic conditions, a social general strike would inevitably lead to a violent revolutionary conflict in which the whole power of the state would be at stake. But experience has shown that a general strike can play an important, and sometimes decisive, part as a first step in a political revolution or even in a social revolution. But even in such cases, the final success of the movement depends on the capacity of the revolutionary forces to assume and hold power and organize the economic life of the country.

The most important case of revolutionary direct action before 1914 was the general strike in Russia from Oct. 17 to Nov. 1, 1905, in which not only the workers but many professional and middle class groups took part. The tsarist government was severely shaken and granted to the people extended suffrage and an effective constitution. But the government soon recovered from its first shock and tried to withdraw some of the concessions made. In reply, the St. Petersburg soviet, or Council of Workers' and Peasants' Deputies, which had become the recognized revolutionary authority, called a second general strike on Nov. 14, 1905. The government this time merely stood aside and allowed the workers to feel the full brunt of the consequent hunger and disorganization. As the soviet had no troops and therefore could not extend the struggle, it had to call off the strike on Nov. 19 without securing concessions. On Dec. 20, 1905, as a result of the arrest of the whole soviet, another general strike was called, which in Moscow turned into an insurrection and was suppressed.

These general strikes had, however, the effect of giving Russia a limited constitutional government and a parliament (Duma) which played some part in resisting extreme tsarist oppression in Russia between 1905-17.

The general strike also played an important part in starting the revolution against the tsar in March 1917 and in the struggle between the moderate Socialist party of Kerensky and the Bolsheviks under the leadership of Lenin and Trotsky in the summer and fall of 1917. But this struggle, which ended in the greatest social revolution in Europe after the French Revolution, soon assumed the form of battles between opposing armies in the field and of battles for the control of the powers of the state (including the secret police) at home. The success of the Bolsheviks was not due to general strikes but to their military triumph over the other groups during 1918-20.

Both the force and limits of the revolutionary general strike

were demonstrated also in the case of Spain during 1933-36. The general strikes of these years were merely one of the methods used by the left groups (left republicans, socialists, communists, and anarcho-syndicalists) in their struggle against the conservative government which they accused of tending toward fascism. The general strikes declared in Oct. 1933 and again in Oct. 1935 developed into violent fighting in the streets and into open revolts which were crushed by the government under Alcalá Zamora, president of the Spanish republic established in 1931. But they had some influence in bringing about the victory of the left in the national elections of Feb. 16, 1936, and in the establishment of the leftist government of Azana.

However, the victory of the left was countered by the revolt of the right under General Francisco Franco, resulting in the civil war which lasted for nearly three years and in which Germany, Italy, soviet Russia and other countries became involved, thus giving the Spanish Civil War the character of a preliminary phase of World War II.

Importance of Direct Action—Historically, the theory of direct action (as the central part of syndicalism) was the early 20th century phase of the struggle between revolutionary and reformist tendencies for the control of the labour and socialist movements of Europe. In national terms, it was a revolt of French socialist and revolutionary ideas which trace back to Louis Auguste Blanqui and Pierre Joseph Proudhon against the Germanic version of Marxism and the Anglo-American views of capitalistic trade unionism. Direct action, in this historic role, was of greatest importance from 1910-14, but it also had considerable influence on the events of 1917-20, including the formation of the communist or Third International.

After 1920, the theory and practice of direct action ceased to be the focus of a distinctive social-revolutionary movement. To the extent to which labour movements in some countries were influenced by revolutionary ideas and aims, they followed the leadership of Russian communism. On the other hand, the labour movements which are reformist and practical in character have adopted some of the methods and slogans of direct action as part of their economic armour but without the original intellectual and emotional tinge. In national terms, revolutionary leadership shifted to soviet Russia with its Bolshevik interpretation of Marxism, while the reformist labour and social movements look for guidance and support to Great Britain and the U.S. The victory of the British labour party in 1945 was expected to strengthen the faith and hope of labour and socialist parties in many countries in the efficacy of parliamentary methods for social reorganization as against the general strike and revolutionary direct action.

Philosophically, the doctrine of direct action is an important strand in the varied texture of current theories as to the nature of class struggle and its relation to social change. The doctrine continues to influence political and sociological students concerned with problems of national sovereignty and the democratic state, with the question of violence as a factor of social evolution and with the impact of group interests on the dynamics of social-economic institutions.

(L. L.)

DIRECT ADVERTISING, a type of advertising distinguished by the fact that it is conducted by delivering by post (mail), by person or otherwise the announcement of an advertiser directly to specific individuals instead of by publishing it in a newspaper or magazine to the public in general. Direct advertising commonly takes such forms as catalogues, sales letters, folders, circulars, broadsides, pamphlets, booklets, post cards, novelty pieces, house organs and package inserts. If any of such material is sent to individuals through the post, such advertising is called direct-mail advertising.

DIRECTIONAL ANTENNA, an antenna having the property of radiating or receiving radio waves in larger proportion along some directions than others. A directional antenna used as a transmitting antenna is sometimes called a "directive antenna." If the angle within which the radiation is substantially confined is a small one the antenna may appropriately be described as a "beam antenna." A type of antenna known as a "coil antenna," consisting of one or more complete turns of wire, has directional characteristics and has the property of radiating or receiving radio waves in larger proportion in angular regions 180° apart than in other directions. One type of directional receiving antenna used particularly at low radio frequencies consists of a comparatively low horizontal aerial having a physical length of the same order of magnitude as that of the signalling waves to be received. Such an antenna is known as a "wave antenna."

DIRECTOIRE STYLE, a loose term designating, in architecture, furniture, etc., the transitional work between the restrained classicism of the Louis XVI style (see LOUIS STYLES) and the Roman heaviness of the Empire style (q.v.), so called from the French directory which was in power 1795-99. The style is characterized by a gradual loss of the delicacy and grace of Louis XVI forms and a growing enthusiasm for purely Roman motives.

DIRECTOR, NAVAL see GUNNERY, NAVAL

DIRECTORS see COMPANY AND CORPORATION LAW

DIRECTORY, literally, that which guides or directs, and hence a book giving directions for public worship, e.g., the *directorium* or *ordo* of the Roman Church. The term now usually signifies a book containing the names, addresses and occupations, etc., of the inhabitants of a town or district, a list of the users of a telephone system or of the members of a particular profession or trade.

The name *Directoire*, or directory, was given to the body which held the executive power in France from Oct. 1795 until Nov. 1799. (See FRENCH REVOLUTION.)

DIRGE, a song or hymn of mourning, particularly one sung at funerals or at a service in commemoration of the dead. It is derived from the first word of the antiphon *Dirige, Domine, Deus meus, in conspectu tuo viam meam* ("Guide, O Lord, My God, My Way in Thy Sight"), of the opening psalm in the office for the dead in the Roman Church.

The antiphon is adapted from verse 8 of Psalm v.

DIRICHLET, PETER GUSTAV LEJEUNE (1805-1859), German mathematician, was born at Duren on Feb. 13, 1805. He was educated at Cologne, and later held professorships at Breslau and Berlin, and in 1855 he succeeded Karl Friedrich Gauss at Gottingen. He became a member of the Berlin academy in 1832 and a foreign member of the Paris academy in 1854. Dirichlet's chief work was on the theory of numbers; he was the first to lecture on this subject at a German university. His researches on complex numbers were published in the *Berichte der Berliner Akademie* in 1841, 1842 and 1846, they were edited by Julius Dedekind in 1863. Dirichlet also wrote on the theory of potential, on equations of the fifth degree and on definite integrals. He wrote a number of memoirs on the work of Gauss, in order to make it more intelligible, but he did not live long enough to complete this work. He died at Gottingen on May 5, 1859.

DIRIGIBLE see AIRSHIP

DIRIGIBLE BALLOON see AIRSHIP

DIRK, a dagger, particularly the heavy dagger carried by the Highlanders of Scotland. The dirk as worn in full Highland costume is an elaborately ornamented weapon, with cairngorms or other stones set in the head of the handle, which has no guard. Inserted in the sheath there may be two small knives. The dirk, in the shape of a straight blade, with a small guard, about 18 in. long, is worn by midshipmen in the royal navy. The origin of the word is doubtful. The earlier forms were *dork* and *durk*, and the spelling *dirk*, adopted by Johnson, represents the pronunciation of the second form. The name seems to have been early applied to the daggers of the Highlanders, but the Gaelic word is *broadag*, and the Irish *durc*, often stated to be the origin, is only

an adaptation of the English word. It may be a corruption of the German *Dolch*, "a dagger." The suggestion that it is an application of the Christian name "Dirk," the short form of "Dieterich," is not borne out, according to the *New English Dictionary*, by any use of this name for a dagger, and is further disproved by the earlier English spelling. In Highland full dress, the *skew dhù*, a small dirk, is carried in the stocking.

DIRSCHAU see TCZEW

DISABILITY, a term used in law to denote an incapacity in certain persons or classes of persons for the full enjoyment of duties or privileges. Thus, persons under age, insane persons, convicted felons, are under disability to do certain legal acts. This disability may be absolute or relative. In the latter case (e.g., drunken or insane persons), the incapable person can not rely on his condition if it was unknown to his contractor at the time the alleged obligation was contracted.

D'ISALGUIER, ANSELME (?b. 1380-1420), French traveller, sometimes considered the first European to have seen the Niger river. According to the *Historia chronologica parlamentorum patriae occitaniae* attributed to Guillaume Bardin, he was a member of a noble family of Toulouse, he reached Gao in 1405, married a native Moslem princess there, then returned to Toulouse with his wife, their daughter, their two sons and some slaves (among them a physician who cured Charles VII. of an illness). The Abbe Tricaud who, in his *Essais de littérature pour la connaissance des livres* (Paris, 1702), records this story, adds that D'Isalguier wrote an account of his travels and produced a dictionary in Arabic, Tuareg and Songhai. The whole episode is considered as true by C. de la Roncière in *La Découverte de l'Afrique au moyen âge*, vol. III (Cairo, 1927). But it was later demonstrated that Tricaud copied the *Annales de Toulouse* of Lafaille (Toulouse, 1687), an extremely unreliable work, which embellished the *Historia chronologica* (itself a forgery). Moreover, a thorough study of the vast documentation concerning the family Ysalguier did not reveal the slightest hint about Anselme.

See F. Galabert, "Le Toulousain Anselme Ysalguier est-il allé au Niger au XV^e siècle?" *Mém. Acad. Sciences Toulouse* (1933), P. Wolf, "Une Famille du XIII^e au XVI^e siècle, les Ysalguier de Toulouse," *Mélanges d'histoire sociale* (Paris, 1942). (P. Wo.)

DISARMAMENT. The word disarmament is used to cover three distinct conceptions: (1) the penal destruction or reduction of the armament of a country defeated in war, (2) the complete abolition of all military armament, and (3) the reduction and limitation of national armament by general international agreement. Disarmament in the first sense is by no means new, but it was enforced most strongly on countries defeated in World War II. Disarmament in the second sense has been advocated by individual thinkers. In the third sense disarmament did not come before an international assembly until The Hague conferences (q.v.) of 1899 and 1907. The failure of these disarmament talks showed how reluctant were the participating powers to reject war as an instrument of national policy.

Disarmament and the 1919 Settlement.—It was partly as a reaction against the conditions of the armed camp of pre-1914 Europe that disarmament was stressed in the making of the Versailles settlement. The fourth of Pres. Woodrow Wilson's fourteen points demanded "adequate guarantees given and taken that national armaments will be reduced to the lowest point consistent with domestic safety." Article 8 of the covenant of the League of Nations changed the word "domestic" to "national" and added to the point of "national safety" the further phrase, "and the enforcement by common action of international obligations." In this way the disarmament problem was linked more directly with the problem of security. The Versailles settlement began by applying the principle of disarmament to the defeated countries, and regulated the number of men, the equipment, transport and armament which they were allowed to maintain. These specific limitations, the results of defeat in war, were related to the general obligations set out in the preamble to part v. of the treaty of Versailles, which expressly declared that "in order to render possible the initiation of a general limitation of the armaments of all nations, Germany undertakes strictly to observe the military, naval and air clauses

which follow" (See VERSAILLES TREATY OF).

Disarmament and the League of Nations.—The attempt to secure agreement on general disarmament through the League of Nations (*qv*) fell into three phases. The first period of committee work and discussions lasted from 1920 to 1925. The second period from 1925 to 1931 was marked by the slow progress of the Preparatory Commission for the Disarmament Conference. The third period from 1932 to 1934 was that of the Disarmament Conference itself. Although the conference was never formally brought to a close, by the beginning of 1935 disarmament had ceased to be a problem in practical politics and many countries had already embarked upon active rearmament programs.

At the beginning of the first period, the assembly of the League took the first step toward implementing article 8 of the covenant. A nongovernmental temporary mixed commission was set up and, after long deliberations, adopted four resolutions, which were in turn accepted by the assembly in 1922. They underlined the principle that disarmament, in order to be effective, must be general. "There can be no limitation without security," said Lord Robert (later Viscount) Cecil, "but there will be no security without limitation." It was on the basis of these resolutions that the commission proceeded in 1923 to draw up the draft treaty of mutual assistance. When this failed to secure adoption, it was replaced by the Geneva protocol of 1924, which set out to offer a threefold guarantee of security—a common definition of aggression, a general system of arbitration and a clarification of the enforcement measures to be taken against aggression—as a necessary preliminary to the calling of a disarmament conference, which, it was suggested, should meet in July 1925. The protocol was warmly welcomed by the assembly in 1924, but failed to secure support from Great Britain to bring it into operation.

In Dec. 1925 the council set up a Preparatory Commission for the Disarmament Conference, which met for the first time in May 1926. Germany and the United States became members at once, and the U.S.S.R. followed a year later. The Preparatory Commission consisted of governmental representatives, assisted by two advisory technical bodies. Progress was slow. Its final session produced a draft convention, which was submitted to the council in Dec. 1930. Qualified agreement was reached on six main points: the acceptance of the principles of budgetary limitation of armament expenditure and of limitation of the period of service, the establishment of a Permanent Disarmament Commission, the limitation of the number of effectives in land, sea and air forces, the acceptance of the method of naval limitations embodied in the London Naval agreement of 1930, and the renunciation of chemical and bacteriological warfare. But these six points were so subject to reservations that they provided little satisfaction even at the time. In Jun. 1931 the council agreed that the Disarmament Conference should open on Feb. 2, 1932, and in May it appointed the then British foreign secretary, Arthur Henderson, as president elect. The interval between the signing of the draft convention and the opening of the conference offered little promise of a future solution. Germany had rejected the draft convention because it upheld the *status quo*. France on the other hand affirmed that respect for the disarmament obligations imposed on Germany in 1919 was the basis of all work for wider disarmament.

The conference was attended by the accredited representatives of 59 states, including five nonmembers of the League. Although the draft convention was accepted as a framework there was little real unity of purpose. The French emphasis was on international control, on the building of a powerful force to assist the League in its work. The British emphasis was on what was called qualitative limitation—the reduction of armament not by numbers but by categories, offensive armament being distinguished from defensive. In practice it proved impossible to secure a universally accepted distinction between the two types. It would be misleading, however, to trace the failure of the Disarmament Conference to an inability to agree on a set of definitions. It soon became clear, as Salvador de Madariaga had written in 1920, that the solution of the problem of disarmament could not be found within the problem itself, but outside it in the wider problem of building an effective international organization.

The most important stages in the history of the conference were the acceptance in July 1932 of a limited agreement by 41 votes to 2 with 8 abstentions: (1) that air attack against civilian populations should be absolutely prohibited and the number of aircraft and civil aviation regulated, (2) that heavy artillery and tanks should in principle be limited in size, (3) that chemical warfare should be prohibited. Germany, along with the U.S.S.R., voted against this agreement and, insisting on equality of status as a condition of continued support, did not attend the second session of the conference, which began in October. It was not until Dec. 11, 1932, that an acceptable agreement was signed, whereby the governments of the United Kingdom, France and Italy declared "that one of the principles that should guide the conference should be the grant to Germany and to other powers disturbed by treaty, of equality of rights in a system which would provide security for all nations."

This attempt to reconcile French demands for security with German demands for equality contained no provisions for its practical application. Germany was brought back to the Disarmament conference, but the deadlock persisted. It was only broken in March 1933 when Ramsay MacDonald, the British prime minister, offered to the conference the so-called MacDonald plan, a five-year draft convention, which for the first time set out disarmament figures for most European countries. Although the plan was received with cordiality, there was continued disagreement in debates, and the conference adjourned again in June 1933, without having reached any new understanding. A French plan, prepared during the recess of 1933, suggested that armament should be stabilized at the existing level for a four- or five-year period. It was accepted by Great Britain and Italy but was strongly opposed by Germany, now under the control of Adolf Hitler. On Oct. 14, 1933, Germany left the Disarmament conference and the League of Nations.

The conference now came to a standstill for six months, and diplomatic negotiations about disarmament produced no results. The publication of the German military estimates in March 1934 diverted attention to the problem of rearmament, and although the conference reassembled again in May 1934, it was in an atmosphere of unreality. Although four commissions were set up in June to deal with problems of regional security, air armament, guarantees of execution and the manufacture of and trade in arms, the central deadlock was complete. From 1934 onward there was a return to power politics, the prelude to World War II.

Naval Disarmament.—Attempts were made between 1919 and 1930, largely on the initiative of the United States, to secure limited naval disarmament. At the Washington conference (*qv*) of Nov. 1921, a Five Power treaty was signed, fixing an arithmetical ratio for large battleships (Great Britain 5, United States 5, Japan 3). It was easier to secure quantitative disarmament in capital ships than in other types of vessel or land armaments (see WASHINGTON TREATY).

In June 1927, Pres. Calvin Coolidge, anxious to cut down U.S. expenditure on armament, called a conference at Geneva to consider the limitation of ships not included in the Washington ratios. France and Italy refused to attend, and the United States and Great Britain soon disagreed. The British delegates insisted that mathematical parity with the United States was not equivalent to practical parity, since British lines of trade and communication were longer, and absolute requirements, particularly in small cruisers, were greater. The conference broke down in August.

The London Naval conference (*qv*) of Jan. 1930 was more successful. The United States, Great Britain and Japan drew up an agreed tonnage table, and together with France and Italy accepted a five-year holiday in the construction of capital ships and a limitation of submarines and aircraft carriers. The international situation after 1931 did not permit any extensive discussion of general naval disarmament. Indeed, the Anglo-German Naval agreement of June 1935 recognized Germany's right to ignore the naval restrictions and prohibitions imposed upon it in 1919.

Disarmament After 1939.—The experience of the breakdown of the disarmament negotiations of the interwar years and the parallel breakdown of collective security led to a more realistic approach to disarmament problems during and after World War II.

The eighth point of the Atlantic charter declared that all nations "for realistic as well as for spiritual reasons, must come to the abandonment of the use of force." It demanded as a first step toward a general system of security the disarmament of aggressor countries. The Moscow declaration of 1943 spoke of "establishing and maintaining international peace and security with the least diversion of the world's human and economic resources" but it also stressed, as did in increased detail the conferences of Yalta and Potsdam, the disarmament of Germany. The charter of the United Nations reflected the increased emphasis on security. The assembly by article 11 was empowered to consider and make recommendations concerning "the general principles of international peace and security, including the principles governing disarmament and the regulation of armaments," and the Security Council by article 26 was made responsible for drawing up specific plans with the assistance of the Military Staff Committee, created by article 47. A further step was taken in Jan. 1946, when the Atomic Energy Commission was set up and given full powers to make plans for controlling not only atomic weapons but also "all other major weapons adaptable to mass destruction." Despite these provisions, the record of achievement in disarmament in the postwar years was not impressive. A high water mark was reached in Dec. 1946, when notwithstanding open differences of approach a resolution was passed unanimously by the assembly, recognizing the necessity for "an early general regulation and reduction of armaments and armed force." The Security Council went on in Feb. 1947 to set up a Commission for Conventional Armaments, which had its first meeting the following month. Both this body and the Atomic Energy Commission failed to reach agreement, and in May 1948 the latter organization suspended its work on the grounds that "agreement on international control is dependent on co-operation in broader fields of policy." Although in Sept. 1948 the soviet delegate at the assembly proposed an all round cut of one third in armament, a long debate on disarmament merely sharpened differences between the Russian bloc and the rest of the powers. There was a virtual impasse in practical disarmament negotiations. It proved impossible to make the Atomic Energy Commission an effective working body, while a resolution passed by the Commission for Conventional Armaments in Aug. 1949, providing for receipt, verification and publication of information about national armament to be operated by an international organ of control within the framework of the Security Council, was vetoed by the soviet government in Oct. 1949. The fourth session of the general assembly of the United Nations, which opened in Sept. 1949, made little headway in its discussion of the problem of either atomic or general disarmament. The political issue overshadowed everything else. (See also OUTLAWRY OF WAR SECURITY.)

DISCANT 366 DISCANT

DISCHARGING ARCH, in architecture, an arch (*qv*) built over an inlet or square-headed opening, so as to take the weight of the wall above off the horizontal head of the opening. In the great pyramid of Giza (c. 3000 B.C.), the entrance passage is roofed with slabs of stone, but above these great blocks, set leaning against each other at the top so as to leave a triangular space beneath, form what is probably the earliest discharging arch extant.

Discharging arches of circular or segmental shape are frequent in Roman buildings, and by the time of Diocletian, the custom of decorating these arches with an architrave had arisen. This usage, which apparently was of Syrian origin, became rather common during a considerable part of the Byzantine period of

architecture.

DISCIPLES OF CHRIST or CHRISTIANS, an American Protestant denomination, founded by Thomas Campbell, his son Alexander Campbell (*qv*) and Barton Warren Stone (1772-1844). Stone had been a Presbyterian minister prominent in the Kentucky revival of 1801, but had revolted because the synod had condemned Richard McNemar, one of his colleagues for preaching (as Stone had done) counter to the Westminster Confession on faith and the work of the Holy Spirit in conversion. He had organized the Springfield presbytery, but in 1804 with his five fellow members signed "The Last Will and Testament of the Springfield Presbytery" giving up that name and calling themselves "Christians." Like Stone, Alexander Campbell had adopted (in 1817) immersion and, like him, his two great desires were for Christian unity and the restoration of the ancient order of things. But the Campbellite doctrines differed widely from the hyper-Calvinism of the Baptists whom they had joined in 1813 especially on the points on which Stone had quarrelled with the Presbyterians and after various local breaks in 1825-30 the Reformers were practically all ruled out of the Baptist communion (1832). The Campbells gradually lost sight of Christian unity, owing to the unfortunate experience with the Baptists and to the tone taken by those clergymen who had met them in debates, and for the sake of Christian union it was peculiarly fortunate that in Jan. 1832, at Lexington, Kentucky, the followers of the Campbells and those of Stone (who had stressed union more than primitive Christianity) united. Campbell objected to the name "Christians" as secularized by Stone, but "Disciples" never drove the name out of use.

During the Civil War the denomination escaped in actual session by following the neutral views of Campbell, who opposed slavery, war and abolition. In 1849 the American Christian Missionary society was formed, it was immediately attacked as a "human innovation," unwarranted by the New Testament, by literalists led in later years by Benjamin Franklin (secretary of the missionary society in 1857), who opposed all church music also. Isaac Errett (1820-1888) was the most prominent leader of the progressive party, which was considered corrupt and worldly by the literalists, many of whom, in spite of his strenuous efforts, broke off from the main body, especially in that territory embraced by the states of Indiana, Kentucky, Tennessee, Arkansas and Texas.

The main body appointed in 1890 a standing committee on Christian union, their aim was not for absorption, as was clearly shown by their answer in 1887 to overtures from the Protestant Episcopal Church regarding Christian unity. The credal position of the Disciples is simple: great stress is put upon the phrase "the Christ, the Son of the living God," and upon the recognition by Jesus of this confession as the foundation of His church, agreement with Baptists is only as to immersion, which is considered "the primitive confession of Christ and a gracious token of salvation" and as being "for the remission of sins," they deny the authority over Christians of the Old Covenant, and Alexander Campbell held this view so forcibly that he was accused by Baptists of "throwing away the Old Testament." The Lord's Supper is celebrated every Sunday, the bread being broken by the communicants. The Disciples are not Unitarian, but they urge the use of simple New Testament phraseology as to the Godhead. The church government of the Disciples of Christ is congregational in character.

Tyler's *History of the Disciples of Christ in vol. xii of "The American Church History Series"* (N.Y., 1894), and article "Disciples of Christ" by H. L. Willett in Hastings, *Encyclopaedia of Religion and Ethics* vol. iv (P. Ar.)

DISCLAIMER, a renunciation or disavowal. In law the term is used more particularly in the following senses: (1) the law of landlord and tenant, the direct repudiation of that relation by the tenant setting up a distinct title either in himself or some third party, (2) in the law of bankruptcy, where the trustee may "disclaim" onerous property (see BANKRUPTCY), (3) in the

law of trusts, the refusal or renunciation of the office or duties of a trustee, (4) in the law of probate, the renunciation, by amendment of specifications, of a portion of an inventor's claim to protection.

DISCONTINUANCE see PRACTICE AND PROCEDURE
DISCONTO-GESELLSCHAFT, BERLIN, established in 1851 as a co-operative credit association, carried on after 1856 in the form of a *commandite* joint stock company all lines of commercial and issuing banking business. By its promoting and issue activities its name was prominently connected with the domestic and colonial economic development. Numerous important German and foreign loans were in the past floated under its auspices.

After 1901 the Disconto Gesellschaft extended its technical organizations beyond Berlin throughout Germany. The taking over of the Norddeutsche bank in Hamburg and of the A. Schaaffhausen'scher Bankverein in Cologne carried its sphere of business also to overseas countries and the Rhenish Westphalian district. After the absorption of the Stahl und Federer A G in Stuttgart (Wurttemberg) and the Bank für Thüringen vorm. B. M. Strupp in Meiningen (Thuringia) the Disconto-Gesellschaft owned 127 branches and branch offices covering the whole of Germany. Participations were furthermore held in the Suddeutsche Disconto Gesellschaft A G, Mannheim, and in the bank firm of L. Pfeiffer, Cassel.

The expansion of the business of the Disconto Gesellschaft led to the establishment of subsidiary banks abroad and participation in other European banks: the Handelsmaatschappij H. Albert de Bary and company in Amsterdam, Kredittbank in Sofia and the bank's interest in the banking firm of Ephrussi and company in Vienna. In overseas countries the Disconto-Gesellschaft founded in conjunction with the Norddeutsche bank in Hamburg the Brasilianische Bank für Deutschland, later Banco Brasileiro Alemão in Rio de Janeiro, with branches in São Paulo, Santos, Porto Alegre, Recife and Salvador, and, further, the Banco de Chile y Alemania, in Valparaíso, with branches in Santiago, Concepción, Temuco and Valdivia. In addition to the foregoing the bank also took an active and leading part in the foundation of the Deutsche Asiatische bank in Shanghai. In Oct. 1929 a merger was arranged with the Deutsche bank (q.v.), the capital and reserves of the Disconto-Gesellschaft then standing at about 186,000,000 reichs marks. (H. Fu.)

DISCOUNT AND DISCOUNT HOUSES In trade a deduction from the price of an article, allowed to a buyer who pays cash, is called a discount. In the money market, the word usually means the rate allowed to the buyer for cash of a bill of exchange due at some future date. For example, if the rate of discount for six months' bills is 4% per annum, the buyer on Jan. 1 of a bill for £1,000 due on July 1 will give £980 for it. The market rate of discount is, to a great extent, regulated by the rate officially announced by the Bank of England or by the central bank in other financial capitals.

Discount houses are companies and firms which specialize in the business of buying and selling the bills drawn on English banks, accepting houses, merchants and others. They make their profit by working with a capital which is small in relation to their total commitments and borrowing large sums from banks and other lenders, employing these sums in the purchase of bills which they either hold until maturity, or, more usually, sell later to the banks or to any other buyer who wants a short and liquid investment. Their rate of profit thus depends on the difference between the rate of interest that they have to pay for the money that they borrow and the rate of discount that they are able to charge to those from whom they buy bills, or which they normally have a large stock in hand.

In the early 1950s the London discount market comprised 1 dozen different houses, nine of which published accounts. The 6 had capital resources (including reserves) totalling 2.7 000 000 and held bills (treasury and commercial) to the amount of about £742 000 000 and government short term bonds amounting to about £311 000 000, making an aggregate portfolio of £1 053 500 000.

Before World War I, the bills handled in the money market consisted almost entirely of those created in the course of trade and private financial operations, but as the amount of treasury bills outstanding increased enormously and as trade was to an increasing extent financed by bank advances, an important part of the business of the discount houses came to be in treasury bills issued weekly by tender. In other centres, where monetary specialization has not been carried so far as in London, discount companies and firms are generally nonexistent or unimportant, but they were successfully developed in New York city, after the establishment of the federal reserve system.

DISCOVERY see PRACTICE AND PROCEDURE

DISCUS THROWING, the art of throwing from a circle 8 ft 2½ in in diameter to the greatest distance, and so that it falls within a 90° sector marked on the ground, an implement weighing 4 lb 6.4 oz known as a discus. The sport was common in the days of Homer, who mentions it repeatedly. It formed part of the pentathlon, or quintuple games, in the ancient Olympic games and is fully described by Statius (*Thebais*, 646-721). Judging by specimens found by excavators, the ancient discus was a circular plate of stone, later of metal, about 8 in or 9 in in diameter, and weighed from 4 lb to 5 lb, although one of bronze, probably a trophy, preserved in the British museum weighs more than 8 lb. To the Greeks discus throwing was a splendid body building.

Throwing the discus was introduced as an event in modern athletics at the revived Olympic games first held at Athens in 1896, and in the same year was instituted as a Swedish championship. The Olympic victor at Athens was R. S. Garrett, U.S., 95 ft 7½ in, and the first Swedish champion, Hejlsjöen, 97 ft 5½ in. Thereafter throwing the discus became a recognized event in the athletic championship meetings of all nations. The United States adopted the event in 1897, champion C. H. Henneman, 118 ft 9 in, and England in 1911, champion W. E. B. Henderson, 106 ft 11 in. After World War II the records improved considerably, being world's record, Adolfo Consolini (Italy), Milan, It. (1948), 181 ft 6½ in, Olympic record, Sam Iness (U.S.), Helsinki, Fin. (1952), 180 ft 6½ in, U.S. record, Robert E. Fitch, Minneapolis, Minn. (June 8, 1946), 180 ft 2½ in, English record, H. I. Duguid (1951) 155 ft 3 in. The advance in records resulted from an increasing number of competitors' employing improved technique. The Olympic contests, which set the world's standard, resulted as follows: 1896, R. S. Garrett (U.S.), 95 ft 7½ in, 1900, R. Bauer (Hungary), 118 ft 2½ in, 1904, M. J. Sheridan (U.S.), 128 ft 10½ in, 1908, M. J. Sheridan (U.S.), 134 ft 2 in, 1912, A. R. Taipale (Finland), 148 ft 3 in, 1920, E. Niklander (Finland), 146 ft 7½ in, 1924, L. C. Houser (U.S.), 151 ft 5½ in, 1928, L. C. Houser (U.S.), 155 ft 2½ in, 1932, J. F. Anderson (U.S.), 162 ft 4½ in, 1936, K. K. Carpenter (U.S.), 165 ft 7½ in, 1948, A. Consolini (Italy), 173 ft 2 in, 1952, Sam Iness (U.S.), 180 ft 6½ in. A new world's record was achieved in Tavastehus, Fin., in 1949 when Fortune Gordon (U.S.) made a throw of 186 ft 11 in.

A great deal of discussion has taken place as to the method of throwing the discus employed by the ancient Greeks. Theories have been based upon the description of the sport as given by Statius and upon a reconstruction of Myron's statue of a discus thrower (*discobolus*) which may be seen in the British museum. This statue portrays the thrower in the act of hurling the missile, and Norman Gardner holds that a wrong attitude has been adopted by the restorer R. Tat McKenzie calls the "Greek style," insisted upon at the first modern Olympic games, "absurd and ridiculous," and says it "could never have been in use among the ancient Greeks" (see *Exercise in Education and Medicine*, 1924). F. A. M. Webster (see *Athletics of To Day*), however, contends that the reconstruction is substantially correct and that the discus thrower is correctly posed in the attitude from which commences the turning movement that precedes the delivery of the missile in all modern forms of discus throwing.

The so-called "Greek style" of discus throwing was included at the Athenian celebration, 1906 (Jaervinen, Finland, 115 ft 4 in.), and at the London Olympiad, 1908 (Sheridan, U.S.A., 124 ft 8 in.), but without any great success, so that the event has been abandoned. In the Greek style the thrower places himself upon an inclined pedestal, stretches the arms above the head with the discus held between the hands. He then turns the trunk to the right, bends the body at the waist, allows the right hand holding the discus to swing up behind and places the left hand on the right knee, as in Myron's *Discobolos*. From this position the thrower straightens out his body, hurls the discus forward and leaves the pedestal in the instant of making the throw.

The modern style, which has now entirely superseded the Greek style, provides a more graceful and a more natural series of movements. The essence of this style is that the discus must be slung out and not really thrown at all, the athlete's difficulty lies in controlling an implement which can be retained under and against the hand and wrist only by centrifugal force and such slight pressure as the tips of the fingers are able to exert.

The discus, as used in modern competitions, is composed of a smooth metal rim, permanently attached to a wood body, brass plates set flush into the sides of the wood body, and, in the exact centre of the discus, a means for securing the correct weight, which must be not less than 4 lb 6 oz. The brass plates, circular in form, may not be less than 2 in. nor more than 2½ in. in diameter. The sides taper in a straight line from the beginning of the curve of the rim to a line at a distance of 1 in. from the centre of the discus. The largest dimension comprises a circle not less than 8½ in., the thickness through the centre is not less than 1½ in., and ¼ in. from the edge, not less than ¾ in.

Method of Throwing the Discus.—Preparatory to making a throw the athlete holds the discus in the right (best) hand so that the edge rests against the joints of the fingers nearest to the tips. He takes up his position in the rear half of an 8 ft 2½ in. circle with the feet about 18 in. apart and his left side turned in the direction in which the throw is to be made. The discus is swung lightly back and forth in front of the body below hip level for balance. On the last of the preliminary swings the discus is allowed to follow its own rearward path. As the missile reaches the limit of backward swing the athlete transfers his weight to his left side, which leads the turning action, whereby the circle is crossed, drops his left shoulder to the left and, literally, "falls" into the turn. He makes a half turn upon the ball of the left foot, which is carrying his weight, puts down the ball of the right foot at, approximately, the centre of the throwing circle, transfers his weight to that foot and, on it, makes a further half turn. The arms are still swinging loosely, but the right (throwing) arm is kept well back and the weight of the body retained over the right leg, until the left foot has been placed down at an angle of about 20° to the proposed direction of the throw. So far, a whirl has been used as a contributory factor to the speed with which the actual delivery of the missile will be made. The turn, or whirl, has brought the athlete into the "set" position, which is the most important phase of the throw. From the "set" position the reverse is started by a pull on the discus accompanied by a strong turn of the trunk from the right to a facing-the-front position. The chest and hips are brought square to the front, by the athlete resisting with his left leg, while he turns on the ball of the right foot, so that the flexed right knee turns in and the raised right heel turns outward, until both are in the same direction. The delivery drive from both legs is so violent that the feet leave the ground in this co-ordinated action, and the reverse is so made that the right foot takes the place of the left. Simultaneously, the discus is put into flight over the forefinger (which usually shows a healthy callosity), and the snap of the throwing arm carries the right hand through in the follow-through to about the point of the left shoulder.

DISINFECTANTS, substances employed to neutralize the action of pathogenic organisms and prevent the spread of infectious disease. Putting on one side sunlight, perhaps the best of all disinfectants, these agents may be divided into three classes—1st, volatile or vaporizable substances, which attack impurities in the air, 2nd, chemical agents, for acting on the diseased body or on the infectious discharges therefrom, and 3rd, the physical agencies of heat and cold. Among the first class, formal aldehyde takes foremost place. It acts more rapidly than equal quantities of sulphurous acid, and does not affect colours. It is non-poisonous,

though irritating to the eyes and throat. With the exception of iron and steel it does not attack metals. For destroying vermin sulphurous acid is more powerful than formal aldehyde. Camphor and some volatile oils have been employed as air disinfectants, but mask and do not destroy bad odours. In the second class all antiseptic substances may be reckoned, but the substances chiefly employed are oxidizing agents, as potassium permanganate ("Condy's fluid") and solutions of the so called "chlorides of lime," soda and potash, with the chlorides of aluminum and zinc, soluble sulphates and sulphites, solutions of sulphurous acid, and the tar products—carbolic, cresylic and salicylic acids. Of the physical agencies cold is not practically available by artificial means, heat is used for purifying and disinfecting clothes, bedding and textile substances generally, a temperature of about 250° being employed in the form of steam under pressure. For the thorough disinfection of a sick room all three classes of disinfectants may be required.

DISINTEGRATOR A term rather loosely used, but generally applied to a machine which breaks up and reduces materials by impact, as distinct from one which grinds between rollers, or amongst a mass of loose balls in a rotating drum. There are two

FIG 1—CAGE TYPE DISINTEGRATOR IN WHICH A CAGE OF STEEL BARS REVOLVES WITHIN A CAGE TURNING IN THE OPPOSITE DIRECTION. The cages are enclosed in a steel plate casing (not shown) so that material thrown in is violently hurled about between the bars and broken up into the desired state of fineness.

main classes of disintegrators, the cage or reel and the hammer types, the latter being the more powerful. Among the substances broken up and ground more or less finely in disintegrators are coal, coke, slag, sand, shale, chalk, limestone, pitch, plaster, starch, clay, shells, gypsum, barytes, rock salt, glue, bark, soap, bones, fertilizers, cattle foods, brick bats, stone, limestone, iron oxide, linoleum colours, printer's ink and other products. The more fibrous materials such as bark, rubber, asbestos, leather, herbs, etc., may be shredded up by a machine consisting of a set of revolving knives flying past a set of stationary ones, but in other cases pure

BY COURTESY OF MESSRS. EDGAR ALLEN AND COMPANY LIMITED

FIG 2—HAMMER TYPE DISINTEGRATOR WHICH SMASHES THE MATERIAL INTO SMALL PIECES AGAINST THE BREAKING BLOCKS ANY LARGE CHUNKS UNABLE TO PASS THROUGH THE SCREEN ARE PICKED UP BY THE HAMMERS AND THROWN ONCE MORE AGAINST THE BLOCKS.

impact is the disintegrating medium. The cage machines have a couple of cages, one within the other, composed of steel bars or beaters, which revolve in opposite directions (fig 1). The figure shows the machine with the casing removed, when the stuff is fed through a hopper, it is thrown with great violence amongst the bars and broken up. The speed of revolution ranges in various machines from 300 to 2,000 revolutions per minute. For fine disintegration a machine with duplicated sets of cages is employed.

Hammer or blower which consists of a revolving set of swing-hammers which beat the material small within the casing. The disintegrating action may occur while the material is "in the air," or when it is smashed against steel blocks within the strongly built casing. Fig. 2 shows the latter action, as the hammers whirl round it about a thousand revolutions a minute they catch the stuff fed into the hopper and hurl it against the blocks, the rebound being caught by succeeding hammers, and the material is finally reduced to the fineness required before it can pass through the screen. The inside of the machine is lined with steel plates which can be renewed when worn. Some machines are built with a pocket into which fall any odd pieces of iron (termed *tramp iron*) which accidentally get in with the material. This safety device prevents serious damage to the various parts of the mill. A big crusher will break up 700 tons of limestone in the hour.

DISINTERESTED MANAGEMENT A term historically associated with the regulation and control of the liquor trade, describing a system of management which has for its distinctive object the removal of private profit interest from the sale (in some cases from the manufacture also) of alcoholic beverages. It is not in any sense a prohibitionist system of control. Its object is rather to eliminate from liquor selling the financial inducements which in ordinary trading press for expansion of sales, to bring the motives of trading into harmony with the objects and aim of licensing laws.

In actual practice disinterested management has taken many forms which, although similar in aim, have differed greatly in scope and effect. The underlying principle in every case has, however, been the same. Disinterested management was first adopted on an extensive scale in Scandinavia. It received its earliest statutory sanction in the Swedish law of 1855, which, a few years later, gave birth to the "Göteborg" system of drink regulation, which may be said to have inspired most of the schemes of disinterested management which have since been adopted in different parts of the world. The growth of the system was rapid and the example of Sweden was quickly followed by Norway and Finland. In 1920 the latter country adopted statutory prohibition, but in Sweden and Norway (both spirit drinking countries) disinterested management is now legally established as the sole method of sale for both spirits and wine. The principle has also received statutory recognition in a permissive form in the Danish law of 1924, and in Estonia.

In Great Britain the principle of disinterested management, although lacking explicit statutory sanction (save only in the case of the State management schemes which were organized during the World War), has been variously applied. The earliest experiments date from the late '70s of last century. They were isolated experiments, but notable as pioneer efforts. The first important attempt to apply the principle of disinterested management in Great Britain, was made by the People's Refreshment-House Association Ltd., which has now some 175 licensed houses (chiefly village inns and small country hotels) under its control. It was followed (1900-01) by the organization of Public House Trusts, of which the late Earl Grey was the founder. There are some 14 or 15 of these Trusts in the United Kingdom, of which three are in Scotland and one in Ireland. Most of them are affiliated to a Central Association but operate as separate companies on a county basis. These Trusts have 42 licensed houses under their management and control. In addition there is Trust Houses Ltd.—a separate and unassociated company which is not now organized on a county basis and has 180 houses under its control. All of these Trusts' houses—172 in number (exclusive of the 125 houses controlled by P.H.A.)—are managed on the principle of disinterested management.

There are, also, in the mining districts of Lfeshire and in one or two other Scottish areas, a number of so-called "Göteborg" houses, controlled by local registered companies, in which the principle of disinterested management is applied.

The Carlisle Experiment.—The most complete and important practical application of the principle in Great Britain is, however, represented by the three State management areas in Carlisle and

District, Gretna and Cromarty Firth. In these three areas the liquor trade is under direct Government control and the undertakings have statutory authorization. The Carlisle undertaking is far the most important of the three. It has (save for two hotels and one restaurant) a complete monopoly of the sale of alcoholic liquors in the city of Carlisle and in a large adjacent area, and a partial monopoly in other districts. It also owns and operates the breweries. The undertaking, established in 1916, is directed by a central advisory council, responsible to the Home Secretary, and assisted by a local advisory committee which includes representatives of the local authorities, licensing justices, magistrates, trades council, etc., in the management area. The undertaking is in a sound financial position. By March, 1917, it had repaid, with interest, the whole of the capital liabilities and charges (some £900,000) incurred in the acquisition and development of the properties, and is now a valuable revenue-producing asset, the property of the State, which receives the whole of its profits.

Elsewhere the principle of disinterested management in the form of State control has been adopted on a large scale. In Russia, the State vodka monopoly, founded by M. Witte in 1894, and repealed in 1914 by the late tsar's edict establishing prohibition, has been re-established by the Soviet Government, while in Canada, seven of the nine provinces have substituted Government sale for prohibition. In Poland the State monopoly principle was adopted for spirits in 1914. It applies in the main at present to the production and wholesale distribution of spirits, but includes sale arrangements also. Until 1934 spirits will be sold both in State premises and in private licensed premises. After that date in State premises only. In Germany there has long been a State spirit monopoly, but it is concerned only with the production and wholesale distribution of spirits. (See TEMPERANCE, PROHIBITION, GOVERNMENT LICENSING SYSTEM, LOCAL OPTION.) (A. S. R.)

DISMAL SWAMP, a large marshland lying partly in south-central Virginia and partly in north central North Carolina. Now somewhat reduced by drainage, the original area was about 40 m. long and from 15 to 25 m. wide. The region in which the swamp lies is a slightly undulating plain, with an elevation of from 10 to 20 ft. above sea-level. The maximum elevation is in the heart of the swamp, whither the slope grades toward sea-level. Along the western margin a well-defined ancient sea beach, the Nansemond escarpment, rises from 5 to 50 ft. to constitute a natural boundary. Numerous waterways, most having their source in or near Dismal Swamp, traverse the region.

Drummond Lake, the interior pool, is about seven m. long, and five wide, and 15 ft. deep. Dismal Swamp is the major north-eastern extension of the great palustrine forest which once dominated the landscape of much of the Coastal plain of the United States and of the lower flood plains of its southern streams, a forest characterized by cypress (*Taxodium distichum*), black gums (*Nyssa biflora* and *N. aquatica*), "juniper" (*Chamaecyparis thyoides*), swamp cotton gum (*N. uniflora*) and water ash (*Fraxinus caroliniana*). Not all the area is forest-covered, however, there being extensive bands and patches of marsh grassland as well. The whole area of the swamp may be drained, but the cost of reclamation would probably make it an unprofitable venture. The forest cover has been in large measure removed.

DISORDERLY HOUSE, a house of prostitution, more generally, in law, a house in which the conduct of its inmates is such as to become a public nuisance, or a house where persons congregate to the commission of crime. In England, by the Disorderly Houses Act, 1751, the term includes common bawdy houses or brothels, common gaming houses, common betting houses and disorderly places of entertainment. Under that statute unlicensed places of public entertainment were deemed to be disorderly houses if within 200 ft. of the cities of London and Westminster. Brothels are now dealt with by the Criminal Law

Amendment Acts, 1885 to 1922, and charges can be dealt with summarily, but for a second or subsequent offence the accused can demand trial by a jury. The letting out for gain for indiscriminate prostitution of a room or rooms in a house will make it as much a brothel in law as if the whole house were let out for the purpose. Where, however, a woman occupies a house or room which is frequented by men for the purpose of committing fornication with her she cannot be convicted of keeping a disorderly house (see PROSTITUTION). Gaming and betting houses are prohibited and penalties are imposed by two Gaming Acts, 1845 and 1854, and the Betting Act, 1853.

DISPENSATION, a term with two main applications, (1) to the action of administering, arranging or dealing out, and (2) to the action of allowing certain things, rules, etc., to be done away with, relaxed. Of these two meanings the first is to be derived from the classical Latin use of *dispensare*, literally, to weigh out, hence to distribute, especially of the orderly arrangement of a household by a steward, thus *dispensatio* was, in theology, the word chosen to translate the Greek *oikonomia*, economy, *se*, divine or religious systems, as in the Jewish, Mosiac, Christian dispensations. Dispensation in law is, strictly speaking, the suspension by competent authority of general rules of law in particular cases. Its object is to modify the hardships often arising from the rigorous application of general laws to particular cases, and its essence is to preserve the law by suspending its operation, *se*, making it non-existent, in such cases. It follows, then, that dispensation, in its strict sense, is anticipative, *se*, it does not absolve from the consequences of a legal obligation already contracted, but avoids a breach of the law by suspending the obligation to conform to it, *e.g.*, a dispensation or licence to marry within the prohibited degrees, or to hold benefices in plurality.

1 *Ecclesiastical Law*.—In the theory of the canon law the dispensing power is the corollary of the legislative, the authority that makes laws, and no other, having power to suspend them. The dispensing power, like the legislative authority, was formerly invested in general councils and even in provincial synods, but in the West, with the gradual centralization of authority at Rome, it became ultimately vested in the pope as the supreme lawgiver of the Church. Subject, however, to the supreme jurisdiction of the pope, the power of dispensation continued to reside in the other organs of the Church in exact proportion to their legislative capacities, *se*, in provincial synods in respect of regional rules laid down by them, and in bishops in respect of rules laid down by them for their dioceses. In the earlier periods of the papacy the tendency was to disclaim all authority to make concessions and grant relief from traditional rules, but as time went on and the Church expanded, this rigid attitude proved impossible to maintain, and the principle of "tempering" the law when forced to do so "by the exigencies of affairs or of the times" (*rerum vel temporum angustia*), as laid down by Gelasius (494), was adopted into the canon law itself. The principle was, of course, singularly open to abuse. In theory it was laid down from the first that dispensations were only to be granted in cases of urgent necessity and in the highest interests of the Church, in practice, from the 11th century onwards, the power of dispensation was used by the popes as one of the most potent instruments for extending their influence. Dispensations to hold benefices in plurality formed, with provisions and the papal claim to the right of direct appointment, a powerful means for extending the patronage of the Holy See and therefore its hold over the clergy, and from the 13th century onwards this abuse assumed vast proportions (Hinschius, *Kirchenrecht*, II p. 250). Even more scandalous was the almost unrestrained traffic in licences and dispensations at Rome, which grew up, at least as early as the 14th century, owing to the fees charged for such dispensations having come to be regarded by the Curia as a regular source of revenue (Woker, *Das kirchliche Finanzwesen der Papste*, Nordlingen, 1878, pp. 75, 160). Loud complaints of these abuses were raised in the reforming councils of Constance and Basel in the 15th century, but nothing was done effectually to check them.

The actual practice of the Church is based upon the decisions

of the council of Trent, which left the mediaeval theory intact while endeavouring to guard against its abuses. The proposal put forward by the Gallican and Spanish bishops to subordinate the papal power of dispensation to the consent of the Church in general council was rejected, and even the canons of the council of Trent itself, in so far as they affected reformation of morals or ecclesiastical discipline, were decreed "saving the authority of the Holy See" (*Sess. xxv cap. 21, de ref.*). At the same time it was laid down in respect of all dispensations, whether papal or other, that they were to be granted only for just and urgent causes, or in view of some decided benefit to the Church (*urgens iustaque causa et in major quodammodo utilitas*), and in all cases *gratis*. The payment of money for a dispensation was *ipso facto* to make the dispensation void (*Sess. xxv cap. 18, de ref.*).

Church of England.—By an Act of Henry VIII (1534), it was enacted that neither the king, his successors, nor any of his subjects should henceforth sue for licences, dispensations, etc., to the see of Rome, and that the power to issue such licences, dispensations, etc., "for causes not being contrary or repugnant to the Holy Scriptures and laws of God," should be vested in the archbishop of Canterbury for the time being, who at his own discretion was to issue such dispensations, etc., under his seal, to the king and his subjects. The power of dispensation thus vested in the archbishops partly fell obsolete, partly has been curtailed by subsequent statutes, *e.g.*, the Pluralities Act of 1838. It is now confined to granting dispensations for holding two benefices at once, to issuing licences for non-residence, and in matrimonial cases to the issuing of special licences. The dispensing power of bishops in the Church of England survives only in the right to grant marriage licences, *se*, dispensations from the obligation to publish the banns. Though, however, these licences and dispensations are given under the archiepiscopal and episcopal seals, they are actually issued by the commissaries of faculties and vicars-general (chancellors), independently, in virtue of the powers conferred on them by their patents. This has led, since the passing of the Divorce Acts and the Marriage with a Deceased Wife's Sister Act, to a curiously anomalous position, licences for the remarriage of divorced persons having been issued under the bishop's seal, while the bishop himself publicly protested that such marriages were contrary to "the law of God," but that he himself had no power to prevent his chancellor licensing them.

See article "Dispensation" and kindred topics in the *Catholic Encyclopedia*, in Herzog-Hauck, *Realencyclopädie* (by Hinschius), Wetzer and Welte's *Kirchenlexikon* (2nd ed.), also G. Lichtenberger, *Encyclopédie des sciences religieuses* (Paris, 1878), s.v. "Dispense", and Phillimore, *Ecclesiastical Law*.

2 *Constitutional Law*.—The power of dispensation from the operation of the ordinary law in particular cases is, of course, everywhere inherent in the supreme legislative authority, however rarely it may be exercised. Divorce (in Ireland) by act of parliament may be taken as an example which still actually occurs. On the other hand, the dispensing power once vested in the crown in England is now merely of historical interest, though of great importance in the constitutional struggles of the past. This power possessed by the crown of dispensing with the statute law is said to have been copied from the dispensations or *non obstante* clauses granted by the popes in matters of canon law, the parallel between them is certainly very striking, and there can be no doubt that the principles of the canon law influenced the decisions of the courts in the matter. It was, for instance, very generally laid down that the king could by dispensation make it lawful to do what was *malum prohibitum* but not to do what was *malum in se*, a principle of the canon law, but one difficult to reconcile with English legal principles, since no act is legally *malum* unless forbidden by law. This was pointed out by Chief Justice Vaughan in the celebrated judgment in the case of *Thomas v. Sorrell*, when he rejected the distinction between *malum in se* and *malum prohibitum* as confusing, and attempted to define the dispensing power of the crown by limiting it to cases of individual breaches of penal statutes where no third party loses a right of action, and where the breach is not continuous, at the same time denying the power of the crown to dispense with any general penal law. This judgment, as Sir William Anson points out, only

showed the extreme difficulty of limiting the power ascribed to the crown standing grievance from the time that parliament had risen to be a constituent part of the state. So long as the legal principle by which the law was "the king's law" survived there was in fact no theoretical basis for such limitation, and the matter resolved itself into one of the great constitutional questions between crown and parliament which issued in the Revolution of 1688. The supreme crisis came owing to the use made by James II of the dispensing power. His action in dispensing with the Test act, in order to enable Roman Catholics to hold office under the crown, was supported by the courts in the test case of *Godden v Hales*, but it made the Revolution inevitable. By the Bill of Rights the exercise of the dispensing power was forbidden, except as might be permitted by statute. At the same time the legality of its exercise was admitted by the clause maintaining the validity of dispensations granted in a certain form before Oct. 23, 1689.

DISPERSION see LIGHT
DISPLACED PERSONS see REFUGEES AND THE EXCHANGE OF POPULATIONS

DISPLACEMENT TONNAGE. In shipping, a term used to describe the actual weight of the water displaced by a ship. It is measured by ascertaining the cubic space occupied by that part of the ship which is immersed and dividing this by 35, a ton of sea water measuring 35 cu ft. The term is used to describe the tonnage of warships (see SHIPPING TONNAGE TERMS).

DISRAELI, BENJAMIN see BEACONSFIELD, BENJAMIN DISRAELI, CARL OF

D'ISRAELI (or DISRAELI), **ISAAC** (1766-1848), English man of letters, father of the earl of Beaconsfield (q.v.), was born at Enfield in May 1766. His father, Benjamin D'Israeli, migrated from Venice to London in 1748 and belonged to the London congregation of Spanish and Portuguese Jews.

When Isaac D'Israeli was about 14 his father sent him to live with his agent at Amsterdam, where he worked under a tutor for four or five years. There he studied Bayle and Voltaire, and became an ardent disciple of Rousseau. There also he wrote a long poem against commerce, which he produced as an exposition of his opinions when, on his return to England, his father announced his intention of placing him in a commercial house at Bordeaux. Young D'Israeli was sent to travel in France, and spent some time in literary circles in Paris, returning to London in 1788. A poem printed in the *Gentleman's Magazine*, attacking Peter Pindar (John Wolcott) brought him the friendship of his opponent and of H. J. Pye, who helped to persuade his father that it would be a mistake to force him into a business career. D'Israeli dedicated his first book, *A Defence of Poetry*, to Pye in 1790. Thenceforth his life was passed in the way he liked best—in quiet and almost uninterrupted study. In 1802 he married Maria Basevi, by whom he had five children, of whom Benjamin (afterward Lord Beaconsfield and prime minister of England) was the second. He died at his seat at Bradenham house, Buckinghamshire, on Jan. 19, 1848.

Isaac D'Israeli is the author of the *Curiosities of Literature* (1791; subsequent volumes in 1793, 1817, 1823 and 1834). It is a miscellany of literary and historical anecdotes, of original critical remarks, and of interesting and curious information of all kinds, animated by genuine literary feeling, taste and enthusiasm. He also wrote *Miscellaneous, or Literary Recreations* (1796), the *Calamities of Authors* (1812-13), and the *Quarrels of Authors* (1814). Toward the close of his life D'Israeli projected a continuous history of English literature, three volumes of which appeared in 1841 under the title of the *Annals of Literature*. But of all his works the most delightful is his *Essay on the Literary Character* (1795), which, like most of his writings, abounds in illustrative anecdotes. In the famous "Pope controversy" he supported Byron and Campbell against Bowles and Hazlitt by a defense of Pope in the form of a criticism of Joseph Spence's *Anecdotes* contributed to the *Quarterly Review* (July 1820). In

1797 D'Israeli published three novels, one of these, *Menymnon and Leda*, the *Arabian Petrarch* and *Laura*, was said to be the first oriental romance in English. His last novel *Devotion, or the Fall of the Jesuits*, appeared in 1811, but none of his romances was popular. He also published a slight sketch of Jewish history, especially the growth of the Talmud, entitled *The Genus of Judaism* (1835). He was the author of two historical works—a brief defense of the literary merit and personal and political character of James I (1816), and a learned *Commentary on the Life and Reign of King Charles I* (1828-31).

Of the amiable personal character and the placid life of Isaac D'Israeli a charming picture is to be found in the brief memoir prefixed to the 1849 edition of *Curiosities of Literature*, by his son Lord Beaconsfield.

DISS, a market town in the southern parliamentary division of Norfolk, England, near the river Waveney (the boundary with Suffolk), 95 mi. N.E. by N. from London by the L.N.E. railway. Pop. of urban district (1951) 3,505. The town lies pleasantly upon a hill rising above a mere, which drains to the Waveney, having its banks laid out as public gardens. The church of St. Mary exhibits Decorated and Perpendicular stone and flint work. There is a corn exchange and the agricultural trade is considerable, agricultural implements are manufactured. The poet and satirist, John Skelton (d. 1590), was rector there in the latter part of his life, and is doubtfully considered a native of Diss. Area 6 sq. mi.

DISSEMINATION, of seeds, see **ANGIOSPERMS** *Dissemination*

DISSENTER, one who dissents or disagrees in matters of opinion, belief, etc. The term, from Lat. *dis* *sentire*, to disagree, is, however, practically restricted to the special sense of a member of a religious body in England which has separated from the Established Church, and while it has included English Roman Catholics, who in the original draft of the Relief act of 1791 were styled "Protesting Catholic Dissenters," it is in practice restricted to the "Protestant Dissenters" referred to in sec. 1 of the Toleration act of 1689.

The term is not applied to those bodies who dissent from the Established Church of Scotland, and in speaking of members of religious bodies which have seceded from established churches abroad it is usual to employ the term "dissidents" (Lat. *dis* *cedere*, to dissent). In this connotation the terms "dissenter" and "dis-senting," which had acquired a somewhat contemptuous flavour, have tended since the middle of the 19th century to be replaced by "nonconformist," a term which did not originally imply secession, but only refusal to conform in certain particulars (e.g., the wearing of the surplice) with the authorized usages of the Established Church.

Still more recently the term "nonconformist" has in its turn, as the political attack on the principle of a state establishment of religion developed, tended to give place to the style of "Free Churches" and "Free Churchman." All three terms are now in use (see BAPTISTS, CONGREGATIONALISM, METHODISM, etc.).

DISSOCIATION, a separation or dispersal, the opposite of association but of wider application (see ASSOCIATION). In chemistry the term is given to chemical reactions in which a substance decomposes reversibly in such a way that, from a single molecule of the original substance, two or more smaller molecules are formed. Often these smaller molecules are of different kinds, but sometimes they are of the same kind. Thus the reactions $\text{NH}_4\text{Cl} \rightleftharpoons \text{NH}_3 + \text{HCl}$, and $\text{PCl}_5 \rightleftharpoons \text{PCl}_3 + \text{Cl}_2$ are instances of the first type, $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ of the second. When this breakdown is effected by heating, the process is termed "thermal dissociation." Electrolytic or, as it is termed, ionic dissociation is the separation of a substance in solution into ions (see ELECTRICITY, CONDUCTION OF).

In psychology dissociation is an abnormal condition of the mind wherein the usual connection between various mental elements is lost. Ordinary lapses of memory represent dissociations, in normal minds, between the idea or object which cannot be called to mind and the clue or stimulus idea which formerly sufficed to recall the thing desired. Abrupt changes of mood, or change of

interest from one subject to another, in normal people may represent emotional dissociation. When large, combined groups of ideas and emotions (complexes) become dissociated from other similar groups, the resulting condition is known as dissociation of personality. (See DISSOCIATION). In this condition a successful lawyer has been known to draw all his money from the bank, disappear without reason and subsequently open a small shop in a distant city without memory of his former life.

DISSOLUTION, the act of dissolving or reducing to constituent parts, especially of the bringing to an end an association such as a partnership or building society. A dissolution of parliament in England is the end of its existence (see PARLIAMENT).

DISTAFF, in the early forms of spinning, the "rock" or short stick round one end of which the flax, cotton, or wool is loosely wound, and from which it is spun off by the spindle. The "distaff" or "spindle" side of a family refers to the female branch as opposed to the "spear" or male branch. In 7 the day after Epiphany was formerly known as St. Distaff's day, as women then began work again after the Christmas holiday.

DISTEMPER. A distemper in its simplest form consists of whiting glue (size) and water, and is sometimes called whitewash. The glue acts as a binder, preventing the coatings from rubbing off. Distempers so made are exceedingly cheap, cover well, and are quickly and easily applied with large brushes, but they will not stand washing. They are largely used for whitening ceilings and cheap interior decorative work. When, in course of time the coatings become dirty, it is quite an easy and inexpensive matter to wash them off and apply a fresh coating.

Distempers are sold in the form of a thick paste or jelly, or as a dry powder, and only require mixing with cold or warm water to make them ready for use. A good distemper can be made according to the following recipe. Take 14 lb of gliders' whiting and cover with water. Allow it to stand overnight. Next morning pour off the excess of water and work up well. A small amount of ultramarine blue, mixed with water should be added to the whiting to improve the colour. Add about 5 lb of hot jelly size to the whiting and mix well. Strain through a sieve and it is then ready for use. If it is desired to keep the distemper for any length of time before use a small amount—about 1 oz—of alum or borax should be added as a preservative.

Coloured Distempers—By the addition of coloured pigments to the white distemper a large variety of beautiful shades may be obtained. The pigments used for tinting distempers must be permanent to light and perfectly fast to lime and alkalis. Since they are used largely on cement and plaster walls which contain free lime and alkali, such colours as Prussian blue, chrome yellow, Brunswick green, vermillionette, etc., cannot be used, as the alkali would quickly act on them and destroy their colour. In their place permanent pigments, which are fast to light and alkali, such as ultramarine blue, zinc chrome, Hansa yellow, lime green, Venetian red, etc., must be substituted. The following limeproof colours should, when mixed with 14 lb of white distemper, produce approximately the shades given in the right hand column.

Colours	Tint Produced
6 oz Pale French ochre	Cream
6 oz Lime yellow	Primrose
1 lb Venetian red	Salmon pink
1 lb Venetian red	Terra cotta
1 lb Yellow ochre	
1 lb Venetian red	French gray
1 lb Lime blue	
2 oz Bright lime red	
2 oz Lime blue	Lavender
4 oz Pale lime blue	Bluebell
8 oz Lime blue	Light blue
1 lb Lime green	Sage green
4 oz Yellow ochre	

4 lb Lime green	Apple green
8 oz Lime yellow	Pompeian red
5 lb Bright lime red

Water Paint or Washable Distemper—Although the terms "distemper" and "water paint" are often used synonymously, it is generally accepted that the word "distemper" should be limited to the nonwashable compositions made according to the directions indicated. These simple distempers contain sufficient binder to prevent their rubbing off, but not enough to enable them to stand washing.

The term "water paint," on the other hand, denotes a superior type of modern distemper which contains—in addition to the usual distemper ingredients—a proportion of oil or varnish, which acts as an additional binding agent. With these additional ingredients a good water paint should give insoluble coatings on drying and the coatings should adhere so firmly that they can be washed a few days after application. This property is very valuable as walls coated with these washable sanitary distempers, which have become dirty in course of time, can be easily cleaned and freshened up by simply sponging over with clean cold water.

Water paints have also much better covering and hiding power than the ordinary distempers, because, in addition to whiting, a proportion of lithopone, zinc white or other strong pigment is incorporated, which increases their body or opacity, and gives more solid coatings. Since they contain oils, varnishes, etc., these water paints are sold in paste form only. The paste is of a soft jellylike consistency which only requires mixing with cold or warm water to thin it to a suitable consistency for use.

Water paints are largely used as flat wall paints for interior decoration. They are comparatively cheap and can be obtained in a large variety of beautiful shades. They dry very quickly after application, with a pleasing mat or flat finish, and because of the firmness of adhesion and insolubility of these paints it is possible to apply a second coat a few hours after the first coat has dried, without working up the first coat. This property is very useful in those cases where two or more coats are necessary in order completely to hide the surface which is being painted, and give what is known as a "solid" effect.

Flat distempered surfaces are often "stippled" or dabbed while still wet with a special flat soft hair brush known as the "stippler." By this process all brush marks that might otherwise be in evidence are removed, and the surface is given a beautiful mat velvetlike finish.

When painting large wall areas, as in town halls, council chambers, schools and so on, these water paints are often applied by means of a spraying machine, in this way very large areas can be quickly and successfully covered with the distemper.

Water paints are manufactured as follows. About 10 lb of strong glue or size powder are put in a steam pan, covered with 10 gal of water and left to soak overnight, steam is then passed through till all the glue has gone into solution. The steam is turned off and about 1 gal of linseed oil, copal varnish or mixtures of these is then added, and the whole well beaten until an emulsion is formed. A small proportion of carbolic acid, formaldehyde, or other preservative is added to the emulsion, otherwise it would mould if kept for any long period. This medium—usually known as petrifying liquid—is then mixed while hot with roughly its own weight of white base consisting of whiting, lithopone, blanc fixe, or mixtures of these, and ground through stone mills. The resultant thin paste is then packed in kegs or tins where it sets on cooling to a soft jellylike consistency. The coloured distempers are obtained by adding the necessary quantity of lime fast colour to the white base during the grinding process. There are some paste distempers on the market which are made by using casein—an insoluble white product obtained from skimmed milk—in place of glue or size. In these varieties the casein is dissolved in water with the aid of some alkali, such as carbonate of soda, ammonia or borax, which is added to the water in order to render the casein soluble. The procedure is then carried on in the way already described.

Outside Distempers—For outdoor use only those distempers

should be employed which have been specially made for the purpose. Even when so manufactured these outside distempers (although largely used) will not last more than a year or two and they do not possess the same durability and wearing properties as an ordinary paint.

Outside quality distempers contain more oil than is generally used in the preparation of distempers for indoor use. This helps to bind them better and serves as a protective agent against weathering influences. They should be thinned ready for use with a medium—known as petrifying liquid—which is specially made for this purpose and is of a similar composition to the medium in which the pigments are ground in making the paste distemper.

Powder Distemper—Dry distempers (called calcimines in the U.S.) consist of whiting or carbonate of lime with either finely powdered glue or casein as their binding agent. They are manufactured by grinding the whiting and powdered glue or casein in special grinding and sifting machinery in order to get a thorough incorporation of all the ingredients. Great care must be taken to see that all the materials are thoroughly dry before mixing as even a small amount of moisture present would make the powder clike and set up hard, and of course render it useless. A little borax, silicic acid, alum or other dry preservative is added to keep the dry powder sweet and prevent any decomposition that might take place on standing.

In the case of coloured distempers, sufficient lime fast pigments are incorporated during the mixing process in order to give the desired shade.

These dry distempers are very largely used in both Great Britain and the U.S. on account of their comparative cheapness. The following recipes will give a general idea as to their composition.

1	Whiting	100 lb
	Fine powdered size	8 lb
	Powdered alum	2 oz
2	Whiting	100 lb
	Dry slaked lime	5 lb
	Soda carbonate	2 lb
	Casein	5 lb
3	Whiting	100 lb
	Dry slaked lime	14 lb
	Powdered borax	13 lb
	Casein	12 lb

These white dry distempers may be tinted to any desired shade by adding lime fast colours. (J. G. B.)

DISTEMPER IN ART

Distemper is one of the earliest known mediums of painting. It was used extensively by the Greeks and Egyptians. It consists of a mixture of powdered colour with size and it differs from tempera in which process egg is the medium used. The French call all such mixtures *detrempe* but in England the egg mixture is known as tempera and the size mixture as distemper.

The colours are first ground in water and then mixed at the moment of use with size kept liquid in a *bain marie*. This practice is necessitated by the fact that the proportion of the size required varies according to the nature of the powder used.

The method is useful for quick work as it is fluid and dries rapidly. It is durable though soluble in water. It is used chiefly by scene painters but certain French artists, such as Degas and Jean Edouard Villard, made good use of it.

DISTEMPER see CANINE DISTEMPER

DISTICH, a couplet consisting originally of a hexameter and pentameter line, containing a single idea, as exemplified in the Greek Anthology. Modern examples are to be found in the works of Goethe and Schiller. (See *VERSE*.)

DISTILLATION, an operation involving the conversion of a substance into vapour which is subsequently condensed to the liquid form. It may also be thought of as a process for separating liquid mixtures which depends on the difference in composition between a liquid and its vapour. The process is exemplified in its simplest when steam from a kettle plays upon a cold surface

producing drops of distilled water. The natural cycle by which the water of the oceans passes into the air and later condenses and falls as rain is an example of distillation. The term, which was originally applied to the separation of alcoholic liquors from fermented materials, now has a far wider application, and distillation is an integral part of many chemical manufacturing processes. It has for its object the separation of liquids from non-volatile solids as pure water from the salt in sea water, or the separation of two or more liquids, as gasoline, fuel oil and lubricating oil from crude petroleum.

Simple Distillation—This term is used to distinguish the simplest distillation operations, as illustrated in fig. 1, from the

FIG. 1—TYPICAL LABORATORY DISTILLATION APPARATUS OF SIMPLEST TYPE. THE VAPOUR PASSES FROM THE STILL TO THE LIEBIG CONDENSER WHERE IT IS CONDENSED BY COLD WATER CIRCULATING IN THE WATER JACKET. THE DISTILLATE IS COLLECTED IN THE RECEIVER. RETORTS ARE NOW SELDOM USED.

many possible modifications and elaborations. The basic apparatus consists of three parts: the still or retort in which the liquid is heated, the condenser, to cool the vapours, and the receiver to collect the distillate. On distilling a mixture of substances, the most volatile or lowest boiling distils over first, and the others subsequently or not at all. The simple apparatus described is entirely satisfactory for the purification of a liquid containing nonvolatile material, and reasonably satisfactory for separating liquids of widely divergent boiling points. For laboratory use, the apparatus is commonly made of glass and connected with corks or rubber bungs or ground glass joints. Simple distillation is also used frequently in technology, and for such purposes larger equipment of metal or ceramic ware is used. (See *Distillation in Technology*, below.)

A laboratory distilling flask may be heated by direct gas flame or indirectly through a sand tray or wire gauze, or by electrical means. A thermometer is often used to indicate the progress of a distillation. Its bulb is placed just below the side arm where the vapour leaves the still, so that the thermometer reading approximates the temperature of the vapour. Exact boiling points are best determined in a special apparatus.

An air-cooled elongated side tube is adequate as a condenser with substances boiling above 170° C. For lower boiling substances a Liebig single surface condenser (fig. 1) is used. Many varieties of glass condensers are available, but the chief differences between them are in the ingenuity with which the internal members are designed to give maximum cooling effect.

Historical Note—Distillation appears to have been used by the earliest experimentalists. Aristotle (384–322 B.C.) mentioned that pure water is made by the evaporation of sea water. Pliny the Elder (A.D. 23–79) described a primitive method of condensation in which the oil obtained by heating rosin is collected on wool placed in the upper part of the still. The Alexandrians added a head or cover to the still, and prepared oil of turpentine by distilling pine resin.

The Arabians improved the apparatus by cooling the tube lead-

FIG 2—EARLY DISTILLATION APPARATUS (A) 4TH CENTURY STILL (B) EARLY STILL WITH LARGE REFLEX AREA CONSTANT TEMPERATURE STILL HEAD AND FRACTIONAL CONDENSATION (C) EARLY STILL WITH COOLED HEAD AND PREHEATER

ing from the head, or alembic with water (fig 2). They discovered a number of essential oils by distilling plants and plant juices.

The alchemists used such apparatus to prepare hydrochloric, nitric and sulphuric acids in a relatively pure state.

Early in the 1800s large scale continuous stills for the recovery of alcoholic liquors were devised by J. B. Cellier Blumenthal and Louis Charles Derosne in France, and by Aeneas Coffey in Great Britain. Their bubble plate towers are basically identical with many modern industrial stills. Laboratory practice owed much to the introduction about 1850, of the condenser named (incorrectly) after Justus von Liebig (fig 1).

In the early 1920s the theory of distillation developed earlier by Ernest Sorel was reduced to engineering terms. This stimulated a series of theoretical and practical investigations resulting in such improvement in the efficiency of both industrial and laboratory distillation that separations formerly considered impractical became commonplace. This made distillation one of the most widely used operations in laboratory research analysis and chemical engineering.

Fractional Distillation and Rectification—Fractional distillation was developed because simple distillation is not efficient in the separation of liquids whose boiling points lie close to one another. Originally the term meant the collection of the distillate in successive fractions or cuts. It was also applied to the systematic recombination and redistillation of such cuts in order to improve separation. In modern usage, fractional distillation represents the whole of any process or method whereby the fractions from a distillation are made as different in properties as possible. Especially important in this connection are still heads, columns and condensers (fig 3) that permit the return of some of the condensed vapours toward the still. The whole aim is to achieve the closest possible contact between rising vapour and descending liquid, and so to allow only the most volatile vapour to proceed to the receiver while returning the less volatile material as liquid toward the still. The purification of the more volatile component by contact between such countercurrent streams of vapour and liquid is referred to as enrichment or rectification. The descending liquid is known as reflux.

In modern apparatus reflux is produced by a condenser at the top of a column (fig 3) which is preferably insulated or otherwise made nearly adiabatic and filled with packing or plates (fig 12) or some other device for achieving good contact between vapour and liquid. The most common packings (fig 4A and B) are glass beads, metal chain, Lessing and Raschig rings, Berl saddles, Stedman screens and single and multiple-turn helices of thin wire or glass. A choice among these depends on the diameter of the column and on a balance between cost and efficiency. The Bruun column (fig 4C) is an example of a superior laboratory bubble plate column, but this type reached its greatest development in large-scale technological distillation operations. Other devices involve passage of the countercurrent liquid and vapour streams through the narrow annular space between a tube and a rotating cylinder within the tube.

Either partial or total condensers may be used to produce reflux. In the former, which is also called a dephlegmator, the temperature of the condenser is controlled so that only part of the vapour is liquefied and used as reflux, while the remainder passes on to a second condenser and is collected as product. In total condensers, all the vapour is liquefied. Some of the condensate is removed through a side tube just below the condenser (fig 3) while the remainder supplies reflux. The greater the ratio of reflux liquid to final product (reflux ratio), the better the separation of the various components, but at a corresponding increase in the time and cost of the distillation. Infinite reflux, or total reflux operation, involves no withdrawal of product, and return of all condensate down the column as reflux liquid. Since no distillate is produced, this type of operation is of interest only for testing and for theoretical purposes.

Theory of Distillation—Every liquid or liquid mixture will evaporate into a closed space until the pressure of the resulting vapour reaches a characteristic or equilibrium value. This vapour pressure is a measure of the volatility of the liquid. It has a fixed value for any one liquid at a particular temperature, but always increases with rising temperature. At any particular pressure, a sample of pure liquid will distil completely at a fixed temperature but constancy of boiling point does not prove that the material being distilled is a pure substance. Most liquid mixtures distil over a range of temperatures, but certain compositions of particular mixtures (azeotropes) pass over without change in composition or boiling point. These relations are summarized by the boiling-point curves of fig 5, in which the boiling point of the distillate is plotted against the percentage of the charge that has been distilled. The mixture of liquids with widely divergent boiling points gives a curve with a break at the point where most of the lower boiling component has distilled over. The

sharpness of the break in the distillation curve is determined chiefly by the difference in volatility of the materials being distilled, by the inherent separating power of the column or still head, and by the reflux ratio.

The general theory of distillation is quite complex. For the sake of simplicity the succeeding discussion will be confined to mixtures of two components. Three situations can be distinguished according as the components are (1) quite insoluble in each other—completely immiscible mixtures, (2) soluble only within limits—partly miscible mixtures, (3) soluble in all proportions—completely miscible mixtures.

The first case is illustrated by benzaldehyde and water as discussed under *Steam Distillation*, below. Both components distil together at a temperature below the normal boiling point of either, and in constant proportion until one disappears, after which the other distils alone at its normal boiling point. Partly miscible systems behave similarly as long as two immiscible layers are present, but when one disappears, they behave like a completely miscible mixture.

Three varieties of completely miscible mixtures occur. They are (see fig 6) (A) systems in which an azeotrope has a boiling point greater than that of either pure component—maximum boiling point mixtures, (B) systems in which an azeotrope has a boiling point less than that of either pure component—minimum boiling point mixtures, (C) systems in which all boiling points are intermediate between those of the pure components. Nitric acid (b.p. 56° C) and water (b.p. 100° C) provide an example of (A), the maximum boiling point is 120.5° C for an azeotropic mixture containing 68% of the acid. If a mixture with any other percentage composition is heated, both components pass off in varying amounts until the still contains the azeotropic mixture of maximum boiling point, which then distils unchanged in composition at constant temperature. Propyl alcohol and water furnish an example of (B). On heating this kind of mixture, the azeotrope distils over first, until only one component is left in the still. Thus as a result of their inherent properties, it is impos-

FIG 5—BOILING POINT CURVES FOR TYPICAL LIQUIDS. IF PRESSURE IS CONSTANT THE BOILING POINT RISES AS THE DISTILLATION PROGRESSES EXCEPT WHEN PURE LIQUIDS OR AZEOTROPES ARE BEING DISTILLED. IF THE PRESSURE IS INCREASED OR DECREASED ALL THE BOILING POINTS ARE RESPECTIVELY RAISED OR LOWERED AND THE AZEOTROPE DISTILLING AT THE NEW CONSTANT TEMPERATURE WILL BE OF DIFFERENT COMPOSITION.

FIG 6—THE THREE VARIETIES OF COMPLETELY MISCIBLE BINARY MIXTURES (A) MAXIMUM BOILING POINT MIXTURES (B) MINIMUM BOILING POINT MIXTURES (C) MIXTURES IN WHICH ALL COMPOSITIONS HAVE BOILING POINTS INTERMEDIATE BETWEEN THOSE OF THE PURE COMPONENTS

ble to separate mixtures of (A) and (B) into their pure components by distillation. The difficulties of separating mixtures of (C) are of a different order. Methyl alcohol and water constitute a pertinent example. On distilling any mixture of the two, the distillate always contains a greater proportion of methyl alcohol (the lower boiling component) than the residue in the still. The completeness of the separation of the methyl alcohol from the water depends only on the number of redistillations and the efficiency of the fractionating column.

Theoretical Plates and Plate Efficiency—Fractionating columns are rated according to the number of theoretical plates, and, in the case of plate columns, also according to plate efficiency. A theoretical plate may be defined as one that produces the same difference in composition as exists at equilibrium between a liquid mixture and its vapour. Thus, for example, any portion of a column that produces an improvement in composition from *a* to *b* or *b* to *c*, etc. (see fig 7), is a theoretical plate. On simple distillation of a liquid of composition *a*, the first drop of distillate should have composition *b*. This would be a theoretical or perfect simple distillation. These terms are used since this operation is difficult to achieve in practice because of condensation on the upper walls and neck of the distillation flask. Specially designed apparatus is used to obtain the data for constructing vapour liquid equilibrium curves such as that of fig 7.

The number of theoretical plates is determined from the compositions obtained experimentally at the bottom and top of a

FIG 7—VAPOUR LIQUID EQUILIBRIUM DIAGRAM AND THEORETICAL PLATES

column or a section of column. A common example involves operation at total reflux and use of a vapour liquid equilibrium curve, as may be illustrated by reference to fig 7. Stepwise construction is commenced at the point *a* corresponding to the composition at the still or bottom of the column and continued (along *h*, *i*, *j*, *k*, *l*, *m*, *n*, *o*, *p*, *q*) to the top or distillate composition (*g*). The number of steps required in this construction (four and a fraction in this example) is the number of theoretical plates in the column. The height of the column divided by the number of theoretical plates is called the HETP or height equivalent to a theoretical plate. The more fundamental HTU

FROM A. NORTON, LABORATORY TECHNIQUE IN ORGANIC CHEMISTRY, MCRAW HILL BOOK CO. INC. (1929)

FIG 8—DEVICES FOR COLLECTING FRACTIONS IN VACUUM DISTILLATION

(height of a transfer unit) is determined in a somewhat similar fashion. Practical applications often involve use of more complex graphical procedures and formulas in order to estimate the type and height of column needed to secure a desired separation or purification.

Plate efficiency may be defined as the ratio (in per cent) of theoretical plates to actual plates. Plate efficiencies vary from 10% to more than 100% but with common mixtures having normal viscosities the value is usually between 50% and 75%.

Reduced Pressure or Vacuum Distillation—Distillation under reduced pressure is adopted when dealing with substances which normally boil at inconveniently high temperatures or that decompose when boiling under atmospheric pressure. Vacuum distillation is also sometimes used because it is more economical. The apparatus differs little from that already described except that the distillate receiver must be connected to a vacuum pump and preferably also to a gauge and automatic pressure regulator.

The collection of fractions under reduced pressure is best managed by an arrangement of stopcocks and connecting tubes or by a specially designed multiple receiver which permits removal of one fraction after another without interrupting the distillation or breaking the vacuum (fig 8).

The volume of vapour from a given volume of liquid is 750 times as great at one millimetre pressure as at standard atmospheric pressure (Boyle's law). Hence vacuum distillation is subject to the disadvantage that reduction of the pressure to ten millimetres or less greatly reduces the distilling capacity because of the resistance offered by ordinary apparatus to the easy flow of the very great volumes of vapour. Distillation at pressures below one millimetre is usually carried out in molecular stills (see *Molecular Distillation*, below).

Steam Distillation—This is an alternative method of achieving distillation at temperatures lower than the normal boiling

FIG 9—ANALYTICAL DISTILLATION OF AROMATIC MIXTURE

FIG. 10 SIMPLIFIED DIAGRAM OF CONTINUOUS DISTILLATION. THE PORTION OF THE COLUMN ABOVE THE POINT AT WHICH THE CHARGE IS INTRODUCED IS CALLED THE ENRICHING SECTION AND THE LOWER PORTION IS THE EXHAUSTING SECTION.

point. It is applicable when the material to be distilled is immiscible and chemically nonreactive with water. The usual procedure is to pass steam into the liquid in the still to supply heat and cause evaporation of the liquid. The steam will condense at the still and form a river of water. In fact steam distillation is sometimes carried out by simply adding liquid water to the charge and supplying heat in the usual way. For instance, impure benzaldehyde (oil of bitter almonds) may be purified either by adding water and heating or by passing in steam. As the mixture becomes warm, each liquid vaporizes as if the other were not present; the total pressure of the two vapours is the sum of the individual pressures of the water and benzaldehyde (Dalton's law of partial pressures), as indicated in the accompanying table.

Temper- ture (°C)	Vapour pressure (in mm)			Remarks
	Benzaldehyde	Water	Total	
10	3	12	15	
80	8	352	360	
90	10	510	520	
95	12	600	612	
100	15	760	775	Mixture boils
140	61	760	821	Boiling point of water
150	84	760	844	
170	190	760	950	Approximate boiling point of benzaldehyde

Since any liquid boils when its vapour pressure equals or slightly exceeds the atmospheric pressure (760 mm), the mixture of water and benzaldehyde will boil slightly below the boiling point of pure water and far below that of pure benzaldehyde. The volumes of the two vapours in the vapour mixture will be in the proportion of the vapour pressures, i.e. about 65 of benzaldehyde to 767 of water. The relative weights may be found by multiplying the relative volumes by the corresponding molecular weight. Thus for benzaldehyde, $65 \times 106 = 6890$ and for water, $767 \times 18 = 13806$. It follows, therefore, that benzaldehyde will distil with about two times its weight of water.

Distillation with steam is merely a convenient method of heating and separating the components of a mixture. As a rule, the components are not chemically changed by the process. The components are separated by their different volatilities, and the composition during the distillation is constant. Thus in the case of benzaldehyde, the composition of the vapour is constant throughout the process.

Steam distillation is particularly useful for separating mixtures of two liquids that are partly soluble in water. The components are separated by their different volatilities, and the composition during the distillation is constant. Thus in the case of benzaldehyde, the composition of the vapour is constant throughout the process.

low). It has proved very useful in separating organic compounds with high and nearly identical boiling points, such as the ortho and para isomers.

Azeotropic and Extractive Distillation.—When separation by distillation is especially difficult, because the components of a mixture have almost identical volatilities, improvements can often be achieved by addition of a properly chosen new component. In some instances the choice is a substance which is soluble in the mixture to be distilled and which forms a constant boiling or azeotropic mixture with one or more of the original components. If the volatility of the azeotrope formed from the added component and one substance of the mixture is markedly different from the volatility of the other materials present, ordinary distillation will separate the azeotrope from the remaining components. A familiar example is the preparation of pure anhydrous ethyl alcohol by the addition of benzene to ethyl alcohol containing a small proportion of water. On distillation, an azeotropic mixture containing all the benzene and water passes over with a small amount of alcohol and leaves a residue of anhydrous alcohol. Azeotropic distillation is not practical if the component desired enters into the formation of the azeotrope, and cannot easily be recovered from it.

Extractive distillation is a somewhat similar method. In this process a liquid which is relatively nonvolatile is added near the top of a fractionating column in order to increase the relative volatility of one of the original components and to allow it to distil in a comparatively pure state. Normal butane may thus be separated from butene 2 by addition of acetone, even though the normal volatilities of the hydrocarbons are nearly the same. This separation is of importance in producing raw materials for synthetic rubber and high octane gasoline.

Distillation of Gases.—Gaseous mixtures may be distilled after liquefying them through use of high pressures or low temperatures or both. Once liquefaction is accomplished, distillation may be carried out as usual except that the apparatus must be such as to withstand the abnormal temperature or pressure. Oxygen, nitrogen, neon and the other rare gases are separated from air by liquefaction and distillation at low temperatures. Liquefied petroleum gases are separated and purified by distillation under pressure.

Distillation of Solids—Sublimation.—When solid substances are heated to give gaseous or liquid products, the operation is termed dry distillation. If the procedure involves a breakdown of complex materials into simpler substances (elementary or compound), the process is described as destructive distillation. (See Coal Tar, Tars, Low-Temperature.) Sublimation is a related process in which a solid distils to give a solid without the intervention of a liquid phase.

Analytical Distillation.—A mixture of substances of the same chemical class is often difficult to analyze by conventional chemical methods. Such a mixture may sometimes be analyzed by distillation. Sharp separation between components is essential so that a curve such as that in fig. 9 may be obtained to indicate relative amounts. Analytical distillation has been most useful in studying the composition of petroleum.

Batch and Continuous Distillation.—In most of the previously described varieties of distillation, the material to be distilled (the charge) is introduced into the apparatus at one time before the start of the distillation, and distillate is removed at one point only. All such operations are referred to as batch distillations. In con-

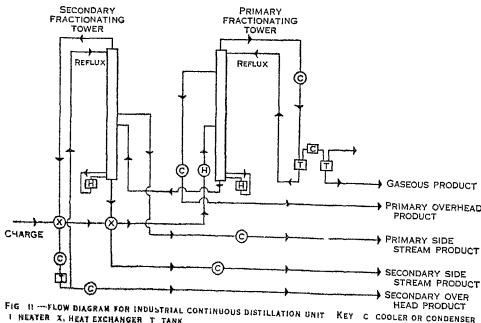

FIG. 11—FLOW DIAGRAM FOR INDUSTRIAL CONTINUOUS DISTILLATION UNIT. KEY: C, COOLER OR CONDENSER; H, HEATER; X, HEAT EXCHANGER; T, TANK.

FIG 12—SECTIONAL DIAGRAMS ILLUSTRATING PLATE CONSTRUCTION AND INTERACTION OF LIQUID AND VAPOUR IN (A) BUBBLE PLATE COLUMN AND (B) PERFORATED PLATE COLUMN

In continuous distillation, the charge is introduced in a constant stream into the side of the column, where part of it descends with the reflux and the remainder is vaporized by the heated vapours rising from the still (fig 12). The most volatile product is concentrated in the overhead product that is removed continuously at the top of the column and the least volatile similarly removed from the bottom. In intermediate fractions are sometimes withdrawn from various levels of the column through side streams. Continuous distillation is seldom used on a small scale, but it is of major importance in industrial operations, particularly in the manufacture of alcohols and petroleum products and in the technology of liquid air.

Distillation in Technology—In addition to the last-mentioned substances, distillation in various forms is used in the processing or production of liquefied fuel gases, coal tar and its products, turpentine, glycerine, fatty acids and a host of other chemical and pharmaceutical

products. These range from butadiene and styrene for synthetic rubber manufacture to formaldehyde, phenol, camphor, etc. The type of apparatus used varies with the nature of the mixture to be distilled, the product, the difficulty of the separations involved, and the means of heating required or available. Equipment is identical in principle with laboratory equipment already described (see figs 11). All varieties of construction materials are used, including particularly cast and wrought iron, copper, mild steel, stainless steel, nickel, monel and aluminum. Lead-lined stills, glass-lined stills, fused silica, glass, structural carbon and stoneware are used where special purity or resistance to corrosion is required.

Stills for batch distillation are usually cylindrical shells. In addition to an outlet to carry away vapours, a cylindrical still is often fitted with (1) a bottom outlet and valve, (2) an agitator for stirring the charge to prevent local overheating, (3) a pressure or vacuum gauge, (4) an inlet and outlet for closed steam coil, (5) a tube reaching to the bottom to introduce live steam, (6) closed tubes to carry thermometers or thermocouples, (7) manholes for charging or cleaning, (8) inspection ports, and (9) a safety valve. In many cases the still has a double bottom and double side walls, forming a jacket for circulation of heating fluid. Steam is most frequently used. It may be passed through the jacket or a coil (closed steam), or sent directly into the liquid to be distilled (open steam). The still may also be heated directly by an open fire of coal, coke, oil or gaseous fuel, but such direct methods have a tendency to local overheating and have been largely superseded.

Indirect heating with steam is subject to closer control. In continuous distillation, pipe stills are most used. The material to be heated is pumped rapidly and continuously through coils or pipes that pass through a furnace. The rapid flow inside the pipes allows higher temperatures and more rapid heating without damaging the pipes or decomposing the charge.

Many industrial distillation set ups consist only of still, vapour line, condenser and receiver, because the liquid mixtures involved are easily separated. A growing number of installations equipped with fractionating towers have come into use. The more efficient towers are either packed or fitted with perforated plates or bubble plate arrangements (fig 13) to give more intimate contact between descending reflux and ascending vapour. Perforated plate towers are particularly useful when the feed material contains solids, as in the distillation of alcohol from fermentation mash. The bubble plate design is by far the most widely used construction. Another device causes descending

liquid to cascade over a wall, while rising vapour forces its way through the cavities.

Large industrial columns may have as many as 100 bubble plates, and diameters up to 3 ft. Two towers may be connected in series to obtain the desired number of plates. There is no theoretical limit to the number of plates, but practical difficulties usually restrict the number in any one unit.

Condensers may be open surface tubular or worm. In the first type, cooling is effected by tricking water over a bank of tubes through which the vapour is passing. A tubular condenser consists of a group of parallel vapour tubes within a shell, through which cooling water flows. A worm condenser involves spiral vapour tubes. Proper choice and design of condensers depends upon rates of heat transfer from the condensing vapours to the cooling water, as well as knowledge of the probable condenser water temperatures and the quantity and character of the vapour to be liquefied.

The cost of distillation operations lies chiefly in the need for continual heat at the still and cooling at the condenser. The pump and ranging means of force combination unit are often quite complex because of the economy of exchanging heat between hot material leaving the pot and cold materials entering it.

Distillation of Water.—Water free from dissolved salts is unobtainable in many scientific and industrial operations. The pot stills consist of a boiler, fed by warm water from the condenser, and suitable devices for eliminating entrainment. The condenser and still receivers are usually of tin, or at least tin-plated. Ordinary glass is not suitable for condensing or storing highest purity water. Double distillation is frequently used to ensure removal of traces of impurity. The preparation of very pure water is a laboratory operation requiring greatest care.

The problem of the economic production of potable water from sea water is very old. In 1853 Fitzgerald patented a process for the

"sweetening of sea water." S. Hales (1730) gives a history of the earlier attempts in his book *Philosophical Experiments*. The modern plant consists of an evaporator, distiller and condenser. Condenser tubes may be oval, crescent shaped or indented. The latter are self-scaling. For shipboard use, emphasis is on compactness, whereas multiple effect evaporators of high economy are favoured for use on land.

Compressive Distillation.—During World War II pure water was produced by compressive distillation characterized by very high fuel economy (175 lb distillate per 1 lb of fuel). The steam from boiling sea water is slightly compressed and circulated through a coil in the still. The compression raises the temperature of the steam sufficiently to allow it to maintain the charge of sea water at its boiling point. The temperature loss to the still cools the steam and condenses it to distilled water. No separate condenser or cooling water is required. The principle is applicable to distillation of substances other than water.

BIBLIOGRAPHY.—Laboratory distillation is discussed in all books on practical organic chemistry, and its theory in treatises on physical chemistry and chemical engineering. See A. C. Morton, *Laboratory Technique in Organic Chemistry* (1938), C. C. Ward, *Review of the Literature on the Construction, Testing, and Operation of Laboratory Fractionating Columns*, U.S. Bureau of Mines technical paper no. 5600 (1919), C. S. Robinson and E. R. Gilliland, *Elements of Fractional Distillation*, 4th ed. (1950), takes up the application of the principles to the problems of industrial design and operation. The standard older text is S. Young and collaborators, *Distillation Principles and Processes* (London, 1924). Section 25 of vol. 2, pp. 1541–1670, of *The Science of Petroleum* (London, 1938) is devoted to a discussion of distillation. Descriptions of industrial procedures and equipment can be found in the technological literature of particular substances. (A. RE.)

MOLECULAR DISTILLATION

When the high-vacuum still is constructed so as to impose no hindrance to the passage of vapour from evaporator to condenser, a device known as the molecular still is achieved. Distillation occurs in this still at the lowest temperatures believed possible. Unstable substances which can be purified by no other means of distillation can often be treated without harm in the molecular still. The apparatus takes many forms but the simplest, which typifies the action of all the others, is little more than a flat vessel, like two saucers sealed together, which is held under high vacuum. The material to be distilled is heated in the lower saucer and the vapour condenses on the upper, cooled saucer. The saucer arrangement and two practical molecular pot stills for laboratory use are shown in fig. 13.

The names of many inventors are associated with the origins of molecular distillation. The first record of a truly molecular apparatus, where the evaporating and condensing surfaces were separated by a distance less than the free paths of most of the vaporized molecules, is the mercury still of J. N. Bronsted and G. von Hevesy (*Fid. Mag.*, 1922). The first truly molecular still for the separation of heavy organic substances was described by C. R. Burch (*Nature*, 1928). Early molecular distillations were performed by H. I. Waterman (1919) in the Netherlands, by E. W. Washburn at the bureau of standards in Washington, D.C. (1919), and by K. C. D. Hickman (1919) in Rochester, N.Y. The potentially immense value of molecular distillation in processing of natural oils, fats and waxes which could not be distilled by any other known means was pointed out by Burch, and was echoed and implemented by other workers. The three categories of distillands—heavy oils, glyceride fats and natural waxes—accounted for production amounting to more than 5,000,000,000 lb annually in North America, but of this enormous quantity, commercial molecular stills handled only little more than 0.1% at mid 20th century, the capacity however, was expanding rapidly.

The vacuum required for molecular distillation ranges from one to ten one-millionths of an atmosphere which is equal to a pressure of residual air of 0.0075–0.075 mm mercury, or three quarters to seven and one half microns (one micron = $1\mu = 0.01$ mm mercury). Small laboratory stills operate at pressures as low as one half micron, but not nearly so low as pressures erroneously recorded in the literature. Commercial stills operate at about three microns, the advantages of lower pressures being offset by the higher cost of pumping.

The time factor is very important in molecular distillation since the degree of destruction of labile substances is proportional to the duration of exposure in the hot still. All kinds of devices have been employed to reduce the time to the minimum. Early stills exposed the distilland in shallow trays. Then came the falling film still, where the distilland is allowed to tumble down a heated surface contained within an evacuated condenser. The evaporator is generally a vertical polished metal tube heated by electricity, the condenser a large glass tube or ball jar which surrounds and encloses the evaporator. Individual cyclic batch falling-film stills, constructed chiefly of glass, are in use in research laboratories for the multiple recycling and distillation of natural oils. A diagram is shown in fig. 14.

Industrially, the falling film still has been superseded by the centrifugal evaporator. The distilland, generally a natural oil, is fed into the centre of a rapidly rotating metal cone which is warmed on the outside by an electrical radiant heater. The entire assembly is housed within a tank which is maintained under high vacuum by a

FIG 15—CENTRIFUGAL EVAPORATOR (A) DISTILLAND IN (B) METERING PUMP FOR INCOMING DISTILLAND (C) DEGASSING CHAMBER (D) ROTOR (E) CONDENSER COILS (F) DISTILLATE COLLECTING GUTTER (G) DISTILLATE WITHDRAWAL PUMP (H) DISTILLATE OUT (I) DISTILLATE OUT (J) DOME (K) HOUSING (L) HEATER ELEMENTS (M) BEARING HOUSING (N) MOTOR (O) OIL DIFFUSION PUMP (P) OIL BOOSTER PUMP (Q) STEAM EJECTOR PUMPS

train of fast pumps (fig 15). The oil climbs up the inside of the cone under a centrifugal force of 10-100 times gravity and is flung from the upper rim into a stationary gutter whence it flows to a pump which discharges it from the still. The total time of exposure in the hottest zone is about one second. The time of exposure in a high speed laboratory centrifugal still is about 0.2 sec. The reduction in both time and temperature of exposure is so drastic in the latter apparatus that the thermal hazard is diminished about 1,000,000,000,000 times from that of an atmospheric distillation lasting an hour. The improvement over the best industrial flash distillation done at 1 mm mercury is about 1,000,000 times. The improvement factor for the large commercial molecular stills is about 100 times poorer than these figures.

The molecular still requires the service of fast vacuum pumps. Since no economical pump is known that will reduce the pressure a million fold in one operation, it is necessary to employ a number of different kinds of pumps in series. The fastest pump, operating at the lowest pressure is always an oil-vapour condensation pump of the type invented by I. Langmuir (1916) and improved by Burch (1928). It may have self conditioning features introduced by Hickman (1936). The condensation pump pulls residual gases at one to five microns from the still and compresses them 10 to 20 times, discharging them at 0.75 to 15 mm into a fore pump which may be, variously, a large oil-sealed mechanical pump or another oil-vapour booster pump. This latter then discharges into a mechanical pump or steam ejectors.

Uses of the Molecular Still.—The falling film still found commercial use on a small scale in 1935 for the distillation of vitamin A alcohol prepared by the saponification of fish livers. The apparatus came into extended use in 1937 for distilling vitamin A esters from dogfish liver oils and shark liver oils. Centrifugal stills were intro-

in which the term is most frequently used in its legal significance. The power of distress appears to have been derived from the feudal law and to have been substituted for a forfeiture of the tenant's holding. Until the statute 2 and 3 Will. 4 sess. 1 c. 5 the chattels distrained remained only as a pledge in the hands of the landlord and could not be sold.

Rents at common law are of three kinds: rent service, rent charge and rent seck and at common law distress was incident to rent service and by special reservation to a rent charge. A rent reserved by a lease is rent service. Distress was not incident to rent seck until the Landlord and Tenant act 1730. That statute also extended the remedy of distress to rents of assize and chief rents and thereby in effect abolished the most material distinction between them. But a right of distress is not incident to an obligation to pay provided for in an agreement, which is only a licence and does not create the relationship of landlord and tenant between the parties.

All personal chattels are distrainable with the following exceptions: (1) goods absolutely privileged, (2) things in actual use, (3) fixtures (qv), (4) goods delivered to a person in the way of his trade, (5) perishable goods, (6) goods in the custody of the law (e.g., goods already taken in execution by the sheriff), (7) animals *ferae naturae* (dogs and tame deer and deer in an enclosed park may be distrained), (8) crown property, (9) goods of an ambassador or his servants on the premises of an embassy, (10) certain articles covered by special acts of parliament (e.g., gas or water meters), (11) hired agricultural machinery and breeding stock in circumstances coming within the provisions of the Agricultural Holdings act, 1923, (12) goods of an undertenant or lodger (Law of Distress Amendment act, 1908), (13) wearing apparel and bedding of the tenant or his family and the tools and implements of his trade to the value of £5 (Law of Distress Amendment act, 1888), (14) goods conditionally privileged, i.e., privileged if there are sufficient goods of other kinds on the premises to satisfy the distress. (a) implements of trade not in actual use, (b) beasts of the plough and sheep, (c) agisted stock if the Agricultural Holdings act, 1923 applies.

In order to obtain the protection afforded by the Law of Distress Amendment act, 1908, it is necessary for the undertenant or lodger, who seeks protection to make a declaration in writing and serve it on the landlord, his bailiff or agent employed to levy the distress after (not before) the landlord has levied the distress or authorized it to be levied. The declaration must be set out (1) that the tenant has no interest in the goods in question and that they are the property of the person making the declaration, (2) the rent then due by the undertenant or lodger, (3) the rent payable in future and (4) an undertaking to pay all such rent to the landlord until the arrears then distrained for have been paid off. An inventory of the goods in question must be annexed.

A distress for rent may not be made after sunset and before sunrise, nor on a Sunday. It may not be made till rent is in arrear. At common law a distress could not be made after the expiration of the lease, but since the Landlord and Tenant act, 1709, it may be made at any time within six months of the termination. By the National Health Insurance act, 1924, s. 102, where an insured person is receiving sickness benefit under that act and a medical practitioner certifies that the levying of a distress would endanger the insured's life, the levy must be postponed during the currency of the certificate. The certificate is of no effect until it has been sent to the insurance committee and recorded in a special register. It operates for one week but may be renewed

DISTOMUM (see PLATHYHELMINTHES, TREMATODES)

DISTRESS, pressure, especially of sorrow, pain or ill fortune, as a legal term, the action of distraining or distraint the right of a landlord to seize cattle or goods of his tenant for nonpayment of rent, or the right of a person upon whose land cattle stray to seize the cattle "damage feasant" (doing damage). The cattle or goods so seized are taken without legal process as a pledge to compel the satisfaction of a demand or the redress of an injury. They can be retained only until the owner makes satisfaction. "Distress damage feasant" is also applicable to inanimate things on the land, if doing damage thereto or to its produce. Such distress must be made during the actual trespass, and by the person aggrieved by the damage. Distress for rent, however, is the sense

sue for three months but not longer. The register may be inspected without fee. In the cases of premises to which the Rent and Mortgage Interest Restrictions act apply distress cannot be levied without leave of the court.

Six years arrears are recoverable in ordinary cases but if the Agricultural Holdings act applies only one year's arrears are recoverable.

If the tenant become bankrupt the right of distress is limited to six months' rent prior to the adjudication. If more be due that must be provided for in the bankruptcy (Bankruptcy act 1914, s. 57). If a company is being wound up its goods cannot be distrained without leave of the court (Companies [Consolidation] act 1908 ss. 147 and 211).

The distress for rent must be made on the land demised except in the case of the king or queen regnant and except in the case of fraudulent removals and certain rents for quarries in the Forest of Dean. Chattels clandestinely or fraudulently removed from the premises may be followed within 30 days after their removal, unless in the meantime they have been sold bona fide and for valuable consideration. Again if a landlord or his agent goes to distrain cattle which he sees upon the land, and the tenant or any other person drive the cattle off the land the landlord or his agent may follow them, but this does not hold if the landlord or his agent does not see the cattle on the land or the cattle stray from the land of their own volition.

A distress may be made by the landlord himself or a certified bailiff (Law of Distress Amendment act, 1888, s. 7). This certificate is granted by a county court judge. He may be removed by the judge for extortion or misconduct. He should have an authority in writing from his employer called a "distress warrant." This warrant does not require a stamp. The outer door of the tenant's house cannot lawfully be broken open in order to make a distress but if the outer door be open an inner door may be broken open if necessary.

The chattels distrained must be impounded. By the Protection of Animals act, 1911 s. 7 a person impounding any animal must supply it with a sufficient quantity of wholesome and suitable food and water. The landlord cannot sell the chattels distrained to himself. Before any sale takes place inquiry should be made at the county court registrar's office to ascertain whether the goods have been replevied (see REPLEVIN), if that is not so and the rent due and charges for the distress remain unpaid at the end of 5 days (which must be extended at the request in writing of the tenant to 15 days) the goods should be sold for the best price which can be obtained for them (see AUCTIONS and AUCTIONEERS). The surplus, if any, must be repaid to the tenant.

Duties and penalties imposed by act of parliament (e.g., payment of rates and taxes) are also sometimes enforceable by distress.

(A. S. P.)

In the United States, the process is recognized by most of the states for the taking of a personal chattel from the person to secure satisfaction for a demand.

DISTRIBUTION. In economics, the manner in which the income of a community, won by its own production or gained in fruitful exchanges with other communities, is divided up among its members. The national output, or aggregate of services and material goods produced by the capital and labour of a nation, is a continuous stream, which is always flowing and which is divided up among the agents of production in certain shares. The lenders of physical goods take rent, the lenders of capital take interest; management takes profit, labour takes wages or salaries. The national and local governments levy taxes upon all these for the expenses of government, and in so doing change to some extent, large or small, the nature of the distribution among private claimants, as when the taxation of the well-to-do is used to pay an old-age pension. See WEALTH AND INCOME, DISTRIBUTION OF. For distribution in trade see MARKETING.

DISTRIBUTION, IN TRADE: see MARKETING.

DISTRIBUTION OF ANIMALS. A solution of the problems of zoogeography, which attempts to explain the distribution of animals on the earth, may be sought in two directions. We may investigate the distribution of related groups of animals in

the separate regions of sea and land and from this seek to draw conclusions as to former connections between the present habitats of related forms, the historical aspect or we may inquire what animal forms dwell together in places showing certain conditions of environment and by what characters they are adapted to existence under these conditions, the ecological aspect, which is considered here.

For animals to succeed at all, certain general conditions must be fulfilled, if but one is lacking, animal life also is absent. One of these primary conditions is water. No active animal can live permanently in places such as extremely arid deserts, where water supply and dewfall fail completely for long periods.

To many animals light is not immediately necessary. In subterranean caverns, and in the greater depths of the ocean (below 1,700 m.), sunlight is absent, yet animals live in these places provided they can find food. Light is indispensable, however, to green plants since it supplies the energy for the manufacture of organic substances. Animals are dependent on organic food, and so ultimately, upon plants. Light, therefore, is indirectly necessary to animals.

All life is confined within certain limits of temperature. Protein, an important constituent of protoplasm, coagulates at about 70° C. Protoplasm, too, cannot live if its fluid content is frozen, i.e., at temperatures below about -5° C. Thus animal life is absent in the hottest springs (some lower animals, such as Protozoa, rotifers, snails, can live in hot springs of 45°-52° C.), while no animals are present in the perpetual snows of mountains.

Food is absolutely essential to all animals. In addition to organic materials (protein, carbohydrates, fats), oxygen is needed, to combine with the products of the breaking down of organic food, and thus liberate energy. There are some places where oxygen and therefore animal life is sparse or absent, in the depths of some seas and in volcanic places where carbon dioxide (CO₂) escapes from the ground, e.g., the floor of the Grotto del Cane at Pozzuoli, near Naples.

The quantity of moisture, warmth and oxygen required by an animal varies in different species, some are able to manage with little, others need much, while others again are frequently indifferent. Animals requiring amounts of moisture, warmth or oxygen (whether great or small) not varying beyond narrow limits are termed stenohygrous, stenothermic or stenoxibiont, respectively, those having wide limits, euryhygrous, eurythermic or euryxibiont. Animals in all respects indifferent are euryoecous, those requiring definite quantities stenoeuous. Euryoecous animals generally have a wider distribution than stenoeuous.

The different regions of the earth occupied by living beings, the sea, fresh water and dry land, are fundamentally different in the conditions they offer and in the demands they make.

Sea.—The sea is the home of life. In it are represented all the structural types in which animal life manifests itself. Echinoderms, tunicates, Cephalopoda, many groups of worms, Radiolaria and Foraminifera are confined to the sea. Myriapoda and

FIG. 1.—MAMMALIAN RED BLOOD CORPUSCLES IN SALT SOLUTIONS.

A 0.2% B 0.75% C 1.0%

Amphibia only are not represented there. Salt water of the concentration of sea water is the optimal medium for protoplasm. Sea water has the same osmotic pressure as the fluid in protoplasm. For that reason it withdraws no materials from the protoplasm neither does it give up any to it. If human blood is examined in salt solutions of strengths such as 0.2%, 0.75% and 1%, the fate of the red corpuscles differs greatly in each case (fig. 1 A-C). In 0.75% NaCl they remain unchanged, this solution is isotonic with the fluid they contain. In 0.2% NaCl the corpuscles give up colouring matter to the salt solution, swell and ultimately burst. (A) In 1% NaCl they shrink (C), water having been withdrawn from them. Animals living in the sea are situated similarly to the corpuscles in the 0.75% salt solution, they need not isolate their inner medium from the environment.

In the sea, too, the conditions of life undergo least change

All seas communicate with one another, and their waters are continually mingled. The salinity, therefore, is about the same in all regions, the temperatures are similar, and vary much less than in fresh water, or in the atmosphere. The amount of oxygen present is very constant. Exceptions are secondary seas having only a narrow connection with the ocean, such as the Mediterranean and Baltic.

Fresh Water—Fresh water, on the contrary, is dangerous to living organisms on account of the small amount of salts contained in solution. As in the red carpiscus in 0.2% NaCl, water is continually passing into the protoplasm. The inward permeation of water may be prevented either by strong armour, as in water insects, the animal body shutting itself off from the environment, or, more frequently, the water that passes in is constantly discharged. Thus all fresh water Protozoa possess a contractile vacuole that contracts rhythmically and discharges water to the exterior. In multicellular fresh-water animals the same result is reached by the action of the kidneys (fig 2).

Fresh water animals, however, have less competition, for only relatively few marine animals are able to counteract the ill effects of fresh water, an advantage that is offset by the invasion of fresh water by many land animals, especially insects.

Land—Terrestrial life offers a number of favourable conditions. Oxygen is present in much greater quantities than in water. Further, dry land, in contrast to the sea, offers abundant vascular plants as food. These advantages, however, are not easily obtained. The amount of moisture in the air is generally far from saturation point, and puts the animals in danger of desiccation. The outer skin, and, above all, the respiratory organs, with their large permeable surfaces, must be protected from excessive evaporation. Only members of three groups of animals can survive life in a dry atmosphere, gastropods, arthropods and vertebrates. The shells of gastropods protect them against desiccation, they emerge only when there is sufficient moisture. Terrestrial arthropods have their chitinous armour. Among the vertebrates, the horny epidermis lessens evaporation. In all three groups the respiratory organs have been removed to the interior of the body. Snails have a pulmonary cavity, millipedes, insects and spiders have internal air tubes (tracheae), air breathing vertebrates have lungs. In all these animals the processes of life take place in the inner albuminous salt solution, not in the atmosphere.

The air also offers a new condition in its lesser density. Water supports the animal body, leaving little work for muscles and supporting organs. In the air, on the contrary, the body must be supported and compact to retain its form. Most terrestrial animals therefore, have skeletons, snails their shells, arthropods their chitinous armour and vertebrates their bony skeletons, various worms, slugs and insect larvae lack skeletons. Further, water supports, or retards the sinking of much floating matter, such as small plants or animals and the disintegration products of organisms (detritus), and this is carried as food to the animal population. For this reason fixed animals may be present in water in great numbers. In terrestrial life, animals must search for their food and fixed forms, except some parasites (e.g., scale insects), do not occur.

Most terrestrial plants cannot be utilized by animals without

undergoing further processes because the protein, fat and starch are all enclosed in a cellulose envelope. Animals, except some protozoans like those that live symbiotically with termites and except further certain annelid worms and some snails (e.g., *Helix pomatia*), possess no ferment in their gastric juice that will dissolve cellulose. The resistant membrane must therefore be broken up to liberate the food. Thus snails tear the cells to small pieces by their radulae, arthropods fragment vegetable food with their jaws, mammals chew with their teeth, and birds grind up food in their gizzards. The numerous herbivores render possible the existence of carnivores, many insects, almost all amphibians and reptiles, and many birds and mammals are insectivorous or predatory.

One particular difficulty to which terrestrial animals are generally exposed is the great variation of temperature. In the sea, the temperature of the water over large areas is subjected only to slight and gradual variations. The daily variations are also slight. In fresh water the temperature does not sink below zero, in deep water it is unusual for it to sink below 4° C. Only in summer in the shallowest basins or in hot springs, does it reach 25°–30° C. On land also there are regions with only slight diurnal and seasonal temperature variations, e.g., tropical forests. The difference between diurnal and nocturnal temperatures, however, is usually considerable and the extreme difference at different seasons at certain places is very large. In central Europe it amounts to 90° F., in Verchojansk (eastern Siberia) it even reaches 180° F. During the winter, life in the sea and in fresh water goes on unchecked, although isolated species hibernate. On land, in the temperate and frigid zones, all life becomes torpid under the influence of winter cold, even the nightly cooling of the air makes many animals sluggish. The organization of terrestrial animals is profoundly influenced by variations of temperature, muscles become stiff, glandular activity ceases. If, however, an animal can produce inside itself by metabolic processes a favourable temperature, and can maintain this through nervous control, it is freed from these temperature variations. Such animals are termed homoiothermal (warm blooded animals). Homoiothermal animals have, nevertheless, to pay a price for this advantage, they become slaves to their increased food requirements. Poikilo-thermal (cold blooded) animals can fast for long periods, a snake or frog can go without food for six months and aestivating snails for four or five years. Hibernators excepted, homoiothermal animals on the contrary, quickly succumb to lack of food.

The Conditions of Dispersal—In the various regions inhabited by living organisms the sea, fresh water and dry land, animal dispersal is influenced in different ways and the barriers opposed to it differ. The seas are in communication with one another in all parts of the earth, though the present connections between the Indo Pacific and the Atlantic are in polar and subpolar regions and on that account are impassable for warm stenothermal animals. For most marine animals, however, dispersal depends on their powers of movement or their capacity for flotation. Sedentary animals can extend their range only during the short free-living larval life, but powerful swimmers like sharks and mackerel are found in all warm seas. Isolation, however, is an important factor in transformation of species. The great variety of marine animals is therefore astonishing, when we consider the similarity of conditions of life in the various seas.

In inland waters conditions are quite different. This region is divided into innumerable small sections such as streams, rivers, lakes and ponds separated by insurmountable obstacles in seas and land. Standing waters in particular are very varied in the materials they hold in solution in conditions of light and temperature, in the fertilizing matter they receive and therefore in their plant life. This wide spread isolation under the influence of environment might give rise to the development of numerous different species, and to great variability within the limits of each species, but actually the fauna of fresh water is very rich in cosmopolitan genera and species and over the whole earth, shows great similarity. The reason for this is the transitory nature of fresh waters. Even in historic times rivers have changed their courses divided and dried up. Small standing waters and even large lakes are

FIG. 2.—A MARINE AND B FRESH WATER ISOPODS. THE BLACK SQUARES SHOWING THE RELATIVE SIZES OF THE NEPHRIDIA (MAXILLARY GLANDS).

FROM A. ROSENTHAL. ZUR VERGLEICHENDE DES BAUES DER NIEREN DER ISOPODEN.

gradually filled with sediment. The existence of enclosed basins is not of sufficient duration for a thorough transformation of the species dwelling in them. Newly arisen waters become populated from those already in existence by organisms that can either fly from one body to the other, or be carried in spores by winds or water birds. It is only in deep and therefore ancient basins that a characteristic fauna has been able to develop, as in Lake Baikal (1706 m deep) and Lake Tanganyika (1535 m).

Dry land is divided into many small, more or less isolated, sections by seas, mountains, deserts and rivers. But terrestrial animals have very variously developed organs of locomotion, and therefore the effect of isolation varies. The great environmental differences have a similarly isolating effect. The transformation of species is thus exceedingly favoured on dry land but is confined to those animals able to live there (mainly gastropod molluscs, arthropods and vertebrates). Nevertheless, 4 of all animal species are terrestrial. We are acquainted with about 3,000 living species of Coleoptera and Echinodermata, animals confined to the sea. On the other hand, nearly 1,000,000 species of insects have been described. But the range of variation among echinoderms and coelenterates is much greater than in the insects.

Prolonged isolation gives a striking character to the animal life of a district. The vicinity of the fauna in the different biotopes arises through transformation of the stock originally present. For that reason the interrelationship of the members of the fauna is much greater than in districts where continual intermixture is possible with forms which wander in from the surrounding regions. Such differentiation is found in the Caspian sea in Lake Baikal, in Madagascar and in South America. In Lake Baikal more than 100 species of planarians (Turbellaria) are found more than half the known species. A third of all the fresh water fishes in South America belong to the family Characidae and include mud and plant eating, and even carnivorous forms. Among mammals the numerous adaptations shown by rodents of the family Hysticomorpha is most remarkable.

Area of Distribution.—The region occupied by a species is known as its area of distribution. The size of the area varies in the different species, it depends on the presence of suitable dwelling places, on the barriers limiting dispersal, on the powers of migration of the species and the facility with which it may be transported on its ecological vehicle and on its history.

Species with restricted range are termed stenotopic, those with wide range, eurytopic. Species becoming extinct, or newly arisen often have a restricted range, examples of the former are the primitive lungfish, *Neoceratodus* (Murray river Australia), and the lizardlike, *Sphenodon* (New Zealand), of the latter, the moth *Cymatophora* or var. *albigenis* in the industrial districts of England and Hamburg. A closely confined habitat also hinders dispersal, such as Lake Baikal and the Hawaiian Islands, with their many endemic species. Changes in the area of a species may take place before our eyes, the jigger flea (*Sarcopsylla p. trans*) first arrived in Africa in 1872, and since that time has spread from the west coast to the east. The lower limit of size of an area varies with the size of the animal and the nature of its food. Large animals are not to be expected on small islands. Carnivores require a larger range than herbivores of the same size. Cosmopolitan species are those present generally over the whole earth wherever they can find suitable dwelling places. (A cosmopolite, however, is not found in all the regions supporting life, i.e., the sea, fresh

water and dry land.) As examples may be mentioned the edible mussel (*Mytilus edulis*), found in all the seas of the world, the brine shrimp (*Artemia salina*) universally present in salt marshes. Broad areas, with other conditions equal, tend to have a richer fauna than occurs in small, circumscribed islands or oases. This is evident when the amphibian and reptilian faunas of various large islands with similar climates are compared.

Animal Communities on a Geographic Scale.—Three main plans exist for the orderly consideration of animal geography on a global scale. The oldest and most generally accepted scheme is the division of the world into faunistic realms, with subdivisions known as regions that are further divided into sub-regions and provinces. The groupings are determined by taxonomic relationships and the whole emphasis is on the fauna, especially birds and mammals historically (i.e., geologically) considered. This is the method of classical zoogeography (see ZOOLOGICAL GEOGRAPHY).

The other two major plans are more ecological in nature. One is based on the distribution of "biotopes" and their associated animal communities. A biotope is a district that shows uniformity in environmental conditions, it is the equivalent of an animal habitat broadly considered. Biotopes are distinguished by physiographic and climatic features and by vegetation. Thus a stretch of rocky coast, or a cave, is a biotope, so also is a pine forest, a savannah or a desert. Biotopes are subdivided into facies and into still smaller environmental niches. They are also grouped into larger units, the largest of which are the three main habitats of living organisms, namely sea, fresh water and land. Though the emphasis in the biotope system is on the environment of animals, its claim for validity in animal geography lies in the fact that regions, uniform in environmental conditions, tend strongly to support a uniform and characteristic animal community. This scheme is outlined in some detail by R. Hesse, W. C. Allee and Karl P. Schmidt (1937).

The third general plan has the biome as its major unit. A biome is based on the concept that the plants and animals associated together in the same area have a certain unity. The biome is thus a plant-plus-animal formation that is composed of a plant matrix together with all associated animals. The larger and more influential animal species may ring the entire area occupied by a biome—including its subdivisions, called associations—and its developmental stages, sometimes these larger animals give unity to the biome, more often the unity is furnished primarily by the vegetation.

On land, biomes coincide with the great landscape types of vegetation. Among the major terrestrial biomes, the following are always recognized: tropical rain-forest, tropical savannah, tropical grassland, temperate deciduous forest, temperate grassland or steppe, desert, coniferous forest and tundra. Inland water and marine biomes are also recognized. The biome of the coral reef is an especially closely knit unit. The general concept is discussed by F. E. Clements and V. E. Shelford (1939), together with a somewhat detailed discussion of the grassland biome of North America.

Whether biomes or their subdivisions are under consideration, the emphasis is on the entire complex community of plants and animals rather than on the habitat—as in the biotope—or on the historic geographic and taxonomic relations of the flora and fauna.

ANIMAL DISTRIBUTION IN THE SEA

The distribution of life in the sea is dependent on factors partly physical, partly chemical. Density and viscosity are the primary factors governing the floating of organisms in the water. (See PLANKTON.) The pressure of the water increases with the depth. A column of sea water of average density measuring 107 m exerts a pressure of one atmosphere per sq m of surface, so that in the greatest known depths of the ocean (10,793 m), a pressure of almost 1,072 atmospheres prevails. The pressure of the water, however, has no perceptible influence on the distribution of the animals. Animal life is present at great depths, and the plankton and fishes of the open sea may undertake, in one night, vertical

Island	Area, sq km	No of Species of Amphibians	No of Species of Reptiles
Borneo	715,100	86	241
Madagascar	591,600	88	181

migrations of 300 m. and more without being injured by alteration of the pressure by about 30 atmospheres. The brittle star, *Ophiothrix sericeum*, is present in depths varying from 6 to 4,370 m., it is eurybathic. Species confined to particular depths are termed stenobathic, e.g., the reef building corals, which flourish only to a depth of 30 m.

Waves—The movements of the water, which at different times and places undergo many changes, are of particular importance to animal life. Waves reach to depths of several hundred metres. Currents may reach similar depths. The breakers make a heavy demand on coastal animal life, in the North Sea the strength of their impact averages 15 tons per sq m. Animals dwelling on rocky coasts within the region of the breakers must protect themselves from injury. This is often accomplished by the animals attaching themselves to the substratum, and by the formation of strong shells. As examples of fixed animals the barnacles (*Balanus*) may be mentioned, others which adhere by a strong foot are the gastropods (*Patella*, *Littorina*), the mussel *Mytilus* anchors itself by its byssus threads. In the deeper layers where movements are felt, sessile animals are able to bend, and have some elasticity of movement, in still waters they are rigid, e.g., the bryozoan, *Caberea boryi*, in the North Sea. Marine currents are very important for the distribution of fixed animals, since they serve as means of transport for the free living larvae.

Temperature—Temperature is very important. The temperature of the surface water decreases, in general, towards the poles, but this is modified by warm and cold currents. The temperature decreases, also, with depth, and at the bottom is down to about zero centigrade. Owing to the great surface currents, more water is carried towards the poles than away from them, and, as the cold water at the poles is heavier than the water of the equatorial regions, there is a steady shifting of the deeper layers towards the equator. These cold, deep currents cannot penetrate secondary seas, like the Mediterranean, separated from the main ocean by ledges not far below the surface.

Related animals show marked variations under the influence of differences of temperature. Frequently the size of individuals of the same species increases with decreasing temperature towards the poles and in deep water layers. The shell of the gastropod *Nassa clausa* reaches a height of 12.7 mm in the Skagerrak, at Spitzbergen it measures 3.8 mm. Similarly, the isopod, *Serolis bromleyana*, measures 16 mm at depths of 730 m. and at 3,600 m. 54 mm. Giant species, i.e., species greatly exceeding related forms in size, are found comparatively frequently in polar seas and in deep water. This may be ascribed to the influence of temperature. The hydrolypoid, *Brachioceranthus imperator*, which attains a height of 2 m. in depths of more than 3,000 m., is an example. Other effects of low temperature are the greater amount of yolk in the eggs, and the frequent occurrence of brood-nursing. The multitude of brood nursing forms in all classes of echinoderms in the Arctic and Antarctic is remarkable. It is noteworthy that the annelid *Cirratulus cirratus*, which in temperate seas deposits its eggs, at the Falkland Islands practices brood-nursing.

The cold waters of the Arctic and the Antarctic are sharply divided from one another by warmer seas. To many cold-stenothermal animals this barrier is insuperable. Eurythermal animals may however, be distributed through all seas, notwithstanding the variety of temperature. The fact that many species present at both poles are absent in the intervening regions has attracted particular attention. Since, in general, the area of a species is continuous, this bipolarity requires explanation. Bipolarity of species is by no means common. Some apparently bipolar species are found in the intervening regions in the cold deep strata, e.g., *Calanus finmarchicus*. In other instances the two polar forms are also related to a species found in the intermediate region. Thus, the bipolar foraminiferan, *Globigerina pachyderma* is related to *G. diutretes* of warm seas. Bipolar species, therefore, are derived from cosmopolitan through parallel modification of peripheral forms under the influence of environment.

Chemical Composition—The chemical composition of the sea is very uniform, in consequence of the general mingling of

the waters. The salinity at a depth of 300 m. is about 3.5% but is lower in surface water in estuaries, and in polar regions when the ice is melting. Considerable variations in salinity are found only in secondary seas shut off from the general mixture of the waters. These have a higher or lower salinity according to the ratio between the amount of river water received and the amount of evaporation taking place. The Red Sea has a high salinity (over 4.0%), so has the Mediterranean (3.8%), the Baltic has a low salinity, decreasing towards the east and north. In the Baltic the influence on the animal population of the decrease in salinity is very striking. The number of species decreases in proportion to the decrease in salinity, in an easterly direction (see TABLE).

Salinity	Marine fishes	Ascidians	Lapellid branch molluscs	Gastropods	Ophiuroids	Amphipods	Decapods
3.5%	Kattegat	20	88	85		113	55
3.0%	Kiel Bay	5	23	17	23	18	9
2.7%	Middle Baltic		6	3		2	
0.4%	Gulf of Bothnia	23	4	1		5	

The size of the species also decreases in the same direction. The edible mussel (*Mytilus edulis*) at Kiel attains a length of 110 mm, further in the Baltic, it measures over 50 mm, in the Gulf of Finland 27 mm, in the Gulf of Bothnia, 21 mm.

The quantity of carbon dioxide, nutritive salts and other materials necessary to plants in the water of any lighted region is particularly important in determining the amount of life. If these materials are abundant, plant life flourishes and consequently animals find plenty of food. The sources of this food are, first, the products of animal metabolism and of the disintegration of dead organisms. Carbon dioxide and nutritive salts are only of use, however, in the upper, illuminated strata of the water, where the light is sufficient to supply energy for the assimilation processes of plants. The dead bodies of organisms that inhabit the open sea sink to the bottom, and, in great depths of the ocean, are withdrawn from the metabolic cycle. Their disintegration products can be used only in shallow seas where mixture of the water takes place right down to the bottom. In deep seas they may be returned to use in places where rising currents bring water from the depths to the surface. It happens, therefore, that coastal regions, shallow seas like the North Sea, and shoals such as the Dogger and Newfoundland banks, show great wealth of life. Rising currents are found chiefly on the west coasts of continents where the surface water is driven away from the coast, and a compensating current from the depths flows towards it. No sea water is so teeming with life as those areas with up-welling water in such regions, e.g., off the coasts of Portugal and Chile. A quantity of fertilizing matter for plants is brought down to the sea, particularly by rivers. The region most richly supplied with river water is the Atlantic Arctic, into which more than half the earth's surface is drained. The Pacific is poorest in this respect, particularly in its eastern portion. Thus, with its great depth, accounts for the poverty of its pelagic life compared with other oceans.

Dissolved oxygen is present everywhere in sufficient quantity in the surface waters of the open sea. In the depths, the influx of currents of polar surface water brings sufficient aeration and, since the disintegration of dead organisms goes on very slowly in the cold water of these depths, oxygen is not used up in the process. In secondary seas where such currents are absent matters are different. In the eastern Mediterranean, the deeper layers of the water lack oxygen, and have a large quantity of carbon dioxide, on this account they contain hardly any life. This also applies to the greatest depths of the Baltic. In the Black sea, some Norwegian fjords, and in Walfisch bay on the west coast of Africa, the bottom water contains hydrogen sulphide produced by the disintegration of organic remains.

The Zones of Life in the Sea—In the major habitat "the sea" two principal regions may be distinguished. These differ com-

pletely in their conditions of life, and, therefore, in their animal population (fig. 3). They are the "benthic region" (floor of the sea) and the "pelagic region" (open sea). The benthic fauna consists of animals attached to the sea bottom. *Pluto* animals are not attached to the bottom, and maintain themselves floating or swimming in the water. Benthic and pelagic regions can be subdivided into two areas, that penetrated by light (on an average from the surface down to 100 m) and a dark or abyssal region

just beneath the surface gazing upwards with eyes situated on the upper surface of the head. The sand also shelters minute animals, which find room for movement between the sandgrains—acoelous turbellarians, Archi Annelida, Tardigrada and Gasterotricha. The principal animals found on the sand are the ophiuroids, some snails, annelids and crabs.

Rocky coasts, in contrast to flat, shifting bottoms, offer a firm substratum for plants (particularly *Laminaria* and *Fucus*), and for sessile animals. Clefts, holes and caves offer shelter from the force of the waves. Sessile animals fix themselves by preference to the kelp and to its places of attachment. Some construct hiding places by boring holes in the rocks, e.g., the boring sponge, *Vano*, the boring bivalves *Pholas* and *Lithodinus* and sea urchins such as *Strongylocentrotus*. Those animals, however, which dwell upon the rock surface, are armoured and protected against attack by hard shells. Sponges have spicules of silica, echinoderms are armoured, and snails and bivalves have strong, often spiny shells. Many crustaceans on rocky bottoms have spiny cuticles. Animals dwelling within the region of the breakers require protection against the battering of the waves, and so are firmly attached (see above). Selection is rigorous in this environment, only a few species can withstand the force of the waves, but this affords them protection from enemies. Thus the edible mussel (*Mytilus*) has a wide distribution in the littoral region, but usually is represented by solitary individuals, in the region of the breakers, however, where they are not exposed to attack, mussels are packed together in large numbers. Softer, more fragile animals—hydroids, worms and small crustaceans among them—live in the interstices, between animals with shells.

Coastal reefs may be compared to rocky coasts. These reefs are raised structures, extending from sea bottom to low tide level, formed by living coral animals and consisting of their calcareous skeletons. These reefs are confined to a belt in the tropical seas, extending about 30° latitude north and south of the equator, since the coral polyps require a temperature of at least 20° C. This accounts for their reduced development on the west coasts of Africa and America, where cold currents narrow the tropical seas. Calcareous algae, Bryozoa, some gastropods and other organisms take part with the corals in the formation of the reef. Reef building corals cannot live below a depth of about 50 m, since they live in symbiosis with algae (*Zooxanthella*), which inhabit the walls of the enteron of the polyp, and require light for assimilation. The delicate colours of corals are obtained from the algae. Many reef-dwelling animals have vivid colours (see Plate). The numerous species of corals of which a reef is composed are so arranged that in the zone of the breakers, strong, resistant forms are found. In deeper water, and in places where there is shelter from the waves, the delicately tinted, branching forms occur. Many kinds of animals find retreats in the numerous holes and cavities of the reefs, among them worms, crustaceans, gastropods and fishes. Some fishes feed on the coral polyps, and bite the ends of the branches with their beak-like jaws (Pomacentridae and Plectognathidae).

Pelagic Zone—The inhabitants of the open water or pelagic region have in common peculiarities connected with floating. Living matter is somewhat heavier than sea water, therefore, to float, animals must possess special adaptations. The rapidity with which a body sinks varies in proportion to its weight. It decreases with increased form resistance (such as expansion of the under-surface). The weight of a living organism is lessened by the sparing use of skeletal material (lime, silica), and by the accumulation of lighter substances (fat, air) in the body. The shells of floating animals, therefore, are small and thin, as in pelagic Foraminifera. The phosphorescent animal *Noctiluca*, many free-swimming crustaceans, the eggs of pelagic fishes (e.g., cod, flat fishes) contain fat globules, further, the accumulation of fat in the liver of many fishes, and the blubber of penguins, seals and whales lessens the effective weight. Air bladders are a highly proficient means of diminishing weight, and are found in many Siphonophora and in bony fishes (Teleostei). Form-resistance is increased by enlargement of the under surface. The most usual way is by absorption of sea water into the body. This does not increase the

FIG. 3—ZOOLOGICAL DIVISIONS OF THE SEA

The illuminated portion of the benthic region is termed the "littoral zone."

Littoral Zone—In the littoral zone the bottom may be firm or shifting. A shifting bottom shows a flat surface, and varies according to its constituents, gravel, sand or mud. Rocks form a hard bottom, and the coast in such places is generally precipitous. The kinds of animals found in the littoral are determined by the type of bottom and by the movements of the water. The littoral is divided into four zones: (1) the spray zone above high tide, (2) the tidal zone between high and low tide marks, (3) the shallow water zone, or region affected by the waves, and (4) the still water zone, which extends from the shallow water zone to the upper limit of the abyssal region, where the benthic region is not reached by effective light.

A pebbly shore in the tidal zone is almost entirely without life, all organisms being killed by friction of the stones against one another. In shallow water, sandy bottoms that are often disturbed are not habitable for many animals. In places, however, where plants (*Zostera*, *Potamogeton*) flourish, the sand is bound together, and animals find hiding places under the leaves and among the roots, sessile animals can find places for attachment, food (mud, detritus) is present, so that here a characteristic fauna is established. In deeper water, and in the shelter of projecting islands and sandbanks, a rich fauna may develop also near the surface, on sand and ooze. Sessile animals, certainly, are not often found on shifting bottoms, owing to the danger of being buried, but oysters settle on the shells of molluscs, or on stones, and the edible mussel (*Mytilus*) attaches itself by its byssus to the floating branches of *Fucus*. On the other hand, shifting bottoms teem with animals that burrow under the surface, and so render themselves invisible to enemies.

In the coastal waters of northern Europe these include the lug worm (*Arenicola*), and other annelids, *Alpheocheilus*, the hemichordate, the heart urchin (*Echinocardium*), numerous bivalves, which usually have smooth, flat shells for digging, and which obtain food and oxygen from the surface by siphons (fig. 4). These are preyed on by starfishes and the predatory snail *Natica*. Crustaceans, amphipods, shrimp and the lancelet, *Amphioxus*, also burrow in the sand. Flat fishes, the stargazer (*Uranoscopus*), weaver (*Tachinus*) and blenny (*Blennius*) work themselves in

FIG. 4—PEPPER MUSSEL (*SCROBICULARIA PIPERATA*) IN SAND

On the left, the inhalant siphon on the right, the exhalant one, clear of water

weight, but distributes it over a greater area. Thus arises the gelatinous tissue frequent in pelagic animals. Water forms 96% of the jelly fish, *Aurelia aurita*. In small animals, the under-surface may be increased by flattening the body, or by horizontally disposed processes which serve as floats, e.g., pelagic nemertines (flattened like cakes), the *Phyllodoce* larvae of crustaceans, copepods (*Sapphirina*). If such means do not suffice, movements are made to assist in the prevention of sinking, as the lashing of the cilia of pelagic larvae, the beating of the ciliated plates of Ctenophora, the muscular movements of crustaceans and fishes. Swimming occurs when the muscular movements are sufficiently strong to render the animal's path independent of the movements of the water. Swimming is almost entirely confined to fishes, some cuttlefishes, and animals not primarily marine, such as turtles, penguins, whales and seals.

Those living organisms that float free in the water are termed the plankton (*q.v.*). The constitution of the plankton of the open sea differs from that of the coastal regions, or of shallow seas. The oceanic plankton consists entirely of forms which pass their whole life floating in the water (holoplanktonic). Examples are Siphonophora, Ctenophora, Chaetognaths, some crustaceans and gastropods, salpae and the ascidian, *Pyrosoma*. In coastal regions, in addition to such holoplanktonic forms, there are numerous animals pelagic only at some period of their life (meroplanktonic), in particular, the larval forms of benthic animals. The composition of the coastal plankton is therefore much more changeable than that of the oceanic plankton. The coastal plankton has its lower limit at a depth of about 200 m, but it may be driven beyond this by storms or currents. Coastal waters are much richer in life than oceanic. In the open ocean, however, the amount of life is not the same in all parts. In the Atlantic, the polar regions are much richer than the tropical. A catch in the tropical Atlantic contained 763 organisms per litre of water, and a comparable catch in cold waters 76,915. There are, however, stretches of tropical seas which have a rich plankton, such as parts of the Indian ocean. The plankton forms the food of many fishes, such as herrings.

Abyssal Region.—The deep, unilluminated, abyssal region of the ocean is not without inhabitants, but plants naturally are absent. Since no building-up of organic substances can take place, the basic food of abyssal animals consists of the dead organisms which sink from the surface. The greater the depth, the less food reaches it. The number of species of the various groups of animals decreases with the depth, the following examples are taken from the crabs in the collective tow-nets of the "Challenger" Expedition.—

Depth, in metres	0-36	36-180	180-360	360-900	900-1800	1800
Number of species	190	75	28	21	3	2

FIG 5.—DEEP SEA BRACHIOPOD
STALK WITH OUTGROWTHS TO WHICH FORAMINIFERA ADHERE

Benthos.—The benthos is composed partly of those animals, which, by setting up eddies in the water, wait food towards themselves, and partly of those feeding on ooze. Echinoderms are particularly numerous among the latter. The soft ooze of the deep sea, which is about the consistency of soft butter, forms a very unstable substratum. For this reason, sessile animals have either long stalks (glass-rope sponges), or their basal end spreads out into root-like processes (horny corals, crinoids brachiopods) (fig 5). Deep water sea-urchins and sea cucumbers (Holothuria) are frequently flattened. Bottom-dwelling crustaceans have elongated legs, the lower surface of which is often broadened by rows of bristles (setae). The power of emitting light is frequently found in animals inhabiting the dark abysses though

it occurs also in the illuminated water layers. Sea pens, horny corals, star fishes and many others emit diffuse light. More than 95% of bathypelagic fishes possess light-producing organs. Nevertheless, light in the depths is scanty. For this reason, the eyes of deep sea crustaceans and fishes are often enlarged, or otherwise made more sensitive. Deep sea animals are of one colour (monochrome), usually violet, dark brown, red or black. The uniformity of temperature conditions and the slight degree of movement of the water favour wide distribution of animals in the deep sea. Many are cosmopolitan, but there are also local species.

THE DISTRIBUTION OF ANIMALS IN INLAND WATERS

While in many respects conditions of life in the ocean are equal, owing to the general intermingling of the waters, those in inland waters show great differences in the various regions. This results from the splitting up of these waters into many larger or smaller sections, and is reflected in the variety of their populations.

The chemical composition of inland waters is very changeable, particularly as regards lime salts. In granite and porphyry regions total dissolved solids may be as little as 16 mg per litre, while in limestone regions they may rise to about 300 mg per litre. Some animals, such as the water flea *Holopedium gibberum*, avoid lime-rich water. Others require it, e.g., most molluscs. The salinity also is very varied. In the Rhine, the water contains 0.14 g NaCl per litre. When the salinity rises above 0.3 g we speak of "salt" water. Lake Balak near the Caspian sea has a salt content of 28.5% and still supports a varied animal community as does Great Salt Lake whose waters are about 23% salt. The lack of life in the Dead sea results from other factors than the high salinity since its waters contain only 23.75% salt. In bog water, the large quantity of humus is unfavourable to life. The amount of oxygen in inland waters varies with time and place. It is highest in the eddying waters of mountain torrents, and in shallow ponds with dense plant growth when exposed to the sun, as this causes the plants to give off much oxygen. On the other hand, in later summer, the oxygen at the bottom of some lakes is completely used up, so that animals like fish that particularly require it cannot live there.

The temperature of inland waters undergoes much greater variations than that of the sea. Inland waters are usually shallow, they are seldom more than 300 m deep, while the majority are not deeper than 10 m. In ponds and pools, the depth is considerably less. There is, therefore, a high ratio of surface to volume, heating and cooling take place rapidly. In temperate regions, a constant temperature is found only in springs welling up from great depths, in deep parts of lakes and in waters in caves, cold-stenothermal animals are found only in such places.

Light does not penetrate so deeply in inland waters as in the sea, on account of their more turbid condition. Usually, it penetrates only 30-40 m, the lower limit of plant life is often at only 7 m or less. In general, shallow waters have more plant life and therefore more animal life than deep ones.

The movements of the water are particularly important to aquatic animals. Flowing water and standing water make quite different demands on their inhabitants, and have therefore different types of population. They differ in chemical composition, thermal conditions, depth and extent. The currents of rivers and other streams prevent the accumulation of matter in solution. Flowing water takes longer to warm, and cools more rapidly than standing water, and the difference of temperature between the surface and the depths is lessened by intermingling. There are, however, intermediate conditions. The rapidity of the current depends on the fall of the land. The Rhine, at its source, has a fall of 2.5% (2.5 m in 100), the upper Rhine from Basle to Bingen about 0.05%, the lower Rhine, 0.12%. The Volga, in its whole course, has a fall of only 0.007%, and the lower Amazon only 0.0019%, they show conditions resembling those of standing water.

Flowing Water.—Flowing waters are almost always connected with the sea. Their animal life, apart from forms not primarily aquatic such as insects and pulmonate gastropods, was originally

derived thence. A continual slow immigration still takes place. Some fishes ascend rivers from the sea only at spawning time (anadromous fishes), e.g., the sturgeon (*Acipenser*) and salmon (*Salmo salar*), others ascend the rivers as young animals and descend to the sea to spawn, e.g., the common eels (*Anguilla*). There are katadromous fishes. Lurlyhalme, marine invertebrates (e.g., copepods, amphipods, oysters) penetrate estuaries, and there mingle with the fresh water inhabitants.

The velocity of river currents may be classed as sluggish, average and rapid, according to the degree of the fall. In sluggish

river erosion is minimal, and deposition of sediment maximal. Fine mud sinks down and forms a nutritious ooze on the bottom. This supports many detritus eaters, such as worms, molluscs and insect larvae. At the average rate of flow, erosion and sedimentation maintain a balance, and the bottom is covered with gravel. In rapid streams erosion prevails, and deposition of sediment is minimal, the bottom is formed of large stones, which, by their movements, would crush to pieces any living organisms among them. The inhabitants must be adapted to this movement of the water. The different stretches of rivers harbour different animal populations. As regards fishes, rivers, from mouth to source, have been divided into the region of carp, of burbot of grayling and of trout. Sharp delimitation, however, is not possible. In slowly flowing waters various kinds of fishes may be present, good swimmers and poor, with rounded bodies or with flat, provided the temperature and amount of oxygen are suitable. The stronger the current, the greater the swimming powers a fish must possess to resist it. In such places, we find fishes predominating which are found in transverse section, and are not so spun round on their axes by the whirling of the waters (fig. 6). The number of species of fish decreases as we approach the source, the continually increasing demands made by currents and falling temperature have a selective influence. This is illustrated by the distribution of fish according to height above sea level in Colorado. Below 1,500 m there are 44 species, between 1,500 m and 2,100 m, 47, this number decreases to 24 between 2,100 and 2,750 m, only 13 species go higher and seven of these are salmonids.

The mountain stream affords the best instance of a characteristic fauna. The animals here take on a certain general stamp, since none can live except those able to accommodate themselves to the severe conditions of temperature and current. All have adaptations which prevent them being swept away by the current. Some are flat, and creep under stones (*Gammarus*, insect larvae), others adhere firmly by a broad sole or sucker (turbellarian worms, gastropods), or with special kinds of suckers (larvae of the gnat *Blépharocera*, fishes and tadpoles of tropical mountain streams), others spin threads which form a strong attachment to the bottom (larvae of the blackfly *Simulium*, pupae of mayflies). They are often flat and depressed to offer the least possible hold to the current. Since they are not strong swimmers, their power of movement is limited compared with that of related forms, e.g., the water-mites of mountain streams do not swim and have limbs without swimming bristles (fig. 7). The inhabitants of mountain brooks are generally eurythermal or cold stenothermal animal communities which require a constant low temperature are found chiefly in springs (the turbellarian *Planaria alpina*, the gastropod *Bythinella dunkeri*).

Standing Inland Waters.—In these regions the absence of currents gives rise to special conditions. An inland basin becomes rich in food material for animals, and in fertilizing matter for plants, brought down by winds and rain. Thus lakes having no outlet are richer in life than those which possess one. In shallow basins, where the bottom is greater in proportion to the water mass than in deep ones, and where in all parts, light penetrates

from top to bottom and permits plant-life, the mass of living organisms is generally greater than in larger and deeper basins. Of 20 Swedish lakes in which this has been studied, the smallest has the largest proportion of fish (113 kg per hectare), the largest (Lakes Wener and Maelar) only 2.7 kg per hectare.

In shallow basins circulation of the water takes place through winds, and thus the lower layers are aerated, as in Lake Balaton in Hungary. In deeper lakes, where no such complete mingling of the water is possible, the lower layers are aerated by convection currents set up by the cooling of the surface water in the cold season. In summer thermal stratification divides many such lakes into three layers: (1) an upper stratum of warm, aerated water, (2) a narrow transition stratum in which the temperature falls rapidly, usually at the rate of 1° C per m, or even faster, (3) the bottom stratum of cool water in which, in lakes rich in organic life, much oxygen is used up in the disintegration of the dead organisms which sink to the bottom, so that the amount of oxygen becomes scanty, or absent. This excludes many animals from such depths and gives a definite character to the composition of the fauna.

Larger basins of such depth that the greater part of the bottom is free from vegetation are described as lakes, in contrast to these are the ponds, pools and puddles, termed collectively small water basins. In lakes we distinguish a shore region (paralimnion), a deep water zone and a region of open water.

The outer portion of the paralimnion, which in summer is occasionally left dry, is poor in life. On the other hand, the deeper paralimnion region where there are plants for food and hiding places is the richest in living organisms.

The open water is populated by plankton, and by fishes that feed on it, e.g., *Alburnus*, *Coregonus*. The bottom fauna is varied. Three types of lakes are distinguished, eutrophic, oligotrophic and dystrophic. The eutrophic type, with flat shores overgrown with vegetation, and with a rich plankton, has its deep layers filled up with putrifying ooze composed of the disintegrating bodies of plankton organisms or detritus. Only animals able to make use of the smallest quantities of oxygen are able to live there, e.g. oligochaetes (Tubificidae), larvae of the mudge *Chironomus*. Both these have haemoglobin in their blood, apparently enabling them to use fully whatever oxygen is present. In oligotrophic lakes with steep banks and little vegetation, the plankton is scanty, and the bottom therefore has less ooze, other insect larvae are found here (*Tanytarsus* larvae). In spite of the greater supply of oxygen, the number of organisms is less because of the smaller amount of food. Dystrophic lakes are those with bog water, in which the acidity caused by humus is unfavourable, and the deficiency in lime also excludes many animals. The plankton in them is chiefly animal, and consists mainly of rotifers and small crustaceans, which feed on colloidal matter in the humus.

In ponds and pools the fauna is similar to that of the overgrown shore zone of eutrophic lakes. Decaying vegetable matter is present in sufficient quantity to provide food and oxygen for the growth of plants and only the great variations in temperature are unfavourable. In pools and puddles there is often a rich fauna of small rotifers, crustaceans and insect larvae. In waters liable to dry up periodically a particularly characteristic fauna is found. In temperate regions these waters are small, but in subtropical steppe areas (South African pans) they are sometimes of much greater extent. In such places animals must pass through stages of development quickly, and therefore must be small, and they need some protection against desiccation. Many produce hard-shelled resting ova (*Hydra*, rotifers, Cladocera) or spores (gemmules of sponges, statoblasts of Bryozoa), others are able to surround themselves by a capsule formed by a glandular secretion (the small annelid *Aelosoma*, some copepods), and some burrow into the ooze and form a capsule of mud around themselves

(phyllopod crustaceans, fishes such as *Protopterus*). Lastly, there are animals that can dry up into a cyst without losing their power of living, such as many rotifers (*Philodina*) and Nematoda (thread worms). These groups can live also in the mossy growth on rocks and tree trunks.

In salt lakes and pools the number of species decreases with increasing salinity. Those able to endure the greatest salinity are the brine shrimp (*Artemia salina*), and a number of fly larvae, but even the brine shrimp suffers changes with increasing salinity, the bristles become stunted, the size of the animal decreases, it becomes enfeebled, and finally disappears.

THE DISTRIBUTION OF TERRESTRIAL ANIMALS

The environmental conditions that influence the distribution of terrestrial animals are much more complicated than those brought to bear on aquatic animals. The chemical composition of the air is not important, as complete intermixture can take place very quickly. More important is the physical condition of the atmosphere, that combination of conditions called climate, and which is not present in water in such complexity. Such climatic factors are atmospheric moisture, temperature, atmospheric movements and solar radiation, some of which change periodically.

Moisture—The amount of atmospheric moisture varies with time and place. Where the air is saturated, as in tropical rain-forests, even soft skinned animals (planarians, leeches) can live out of water without danger of drying up. In such places a rich fauna and flora is found. Life is scarcest in regions where atmos-

perature of air varies to a much greater degree than that of water and does so more rapidly and more extensively. In sea water the lower limit of temperature is about -1.9°C , in fresh water, it is 0°C (32°F). Air temperature may sink to -67.8°C (-80°F) at Verkhoyansk (Verkhoyansk) just north of the Arctic circle in eastern Siberia. The greatest difference between the highest and lowest mean monthly temperatures is also at Verkhoyansk where it amounts to 66.3°C . Daily variations of 31.5°C have been measured at Tucson, Ariz., where the soil surface may reach 71.5°C . Recorded temperatures in Indiana dunes range from 64°C at the surface of the sand in summer to an air temperature of -28°C in winter. Such extremes are characteristic of continental as opposed to oceanic climates.

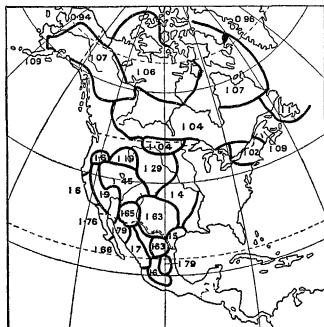

The distribution of animals, therefore, is determined by the degree of warmth they require. Animals limited to a uniformly high temperature, *i.e.*, warm stenothermal animals, in temperate regions live only in particularly warm localities, especially on chalk soil. As examples may be mentioned the green lizard (*Lacerta viridis*), and the praying mantis (*Mantis religiosa*), when found north of the Alps. Cold stenothermal animals, on the other hand, inhabit places with a lower temperature, *e.g.*, snails of the genus *Vitrea* are found on the summits of the Alps, on Mt. Kilimanjaro and in the Cameroons, but are absent in warm parts.

Homiothermal (warm blooded) animals are not immediately influenced by their surrounding temperature. The temperature of the surroundings, however, by its variations renders difficult the regulation of internal heat. The problem of the limitation of the amount of heat given off is solved in various ways. Thick coverings of hair or feathers, or the deposition of fat beneath the skin are the most important, in many birds air sacs assist in maintaining a protective warmth round the internal organs. It is important, also, that the surface area of the body, where heat radiation takes place, should be lessened.

Birds, as compared with mammals, have a very small surface in proportion to mass. Among mammals the external ear and the tail are parts where much heat is given off, and for this reason they are smaller in animals dwelling in cold regions than in their relatives in warmer parts. For instance, the ears of the Arctic fox are small, those of the common fox are larger and those of the desert fox largest (fig. 9).

The length of the ears in comparison with that of the skull in North American hares (*Lepus*), is shown in fig. 8.

Since large animals have a relatively smaller surface area than small ones, this implies in them a diminution of the giving-off of heat. Of two dogs weighing 20 kg and 3.2 kg, having surface areas of 7,500 and 2,423 sq cm respectively, the larger had a surface area of 375 sq cm per kg of body weight, the smaller 757 sq cm, *i.e.*, about double the area, the larger produced in 1 unit of time from 1 kg of mass 45 calories, the smaller 88 calories, the amount of heat given off, therefore, rises in proportion to the surface area. It is worthy of note that warm-blooded animals in cool regions usually attain a larger size than the corresponding species in warmer climates (Bergmann's rule). The coldest parts of a faunal region tend therefore to be centres of maximal forms, while the warmest parts are centres of minimal forms. In the Palaearctic region warm-blooded species have a minimum size on the south coast of the Mediterranean, while in northern Siberia they reach their maximum size. In North America, Alaska is a centre of maximum size, for example—among mammals the bear (*Ursus gyas*), the fox and the moose (*Alces gyas*), among birds, the great horned owl (*Bubo virginianus*), the Alpine lark (*Otocoris alpestris*) and the pine grosbeak (*Pinicola enucleator*), all being larger than normal. Smaller forms are in Florida and Lower California. It should be noted that this rule holds only in a general way, and that there are numerous exceptions and various types of deviation from it.

Peculiarities of Tropical Fauna.—A uniform climate is found chiefly in some tropical regions of the Americas, Africa, India and the East Indies, particularly in tropical forest areas. These are distinguished by the absence of seasonal changes, and by offering optimum conditions of moisture, warmth and light. The abundant vegetation permits rich development of animal life. Poikilothermal animals enjoy almost the same favourable conditions as have been established internally as the optimum in homeothermic animals. Such animals require considerably less food than in temperate regions. Many classes of poikilothermal animals attain a considerable size in the tropics, e.g., numerous insects, millipedes, spiders, snails. There amphibians and reptiles attain maximum size. Brilliant colours and clearly defined markings are characteristic of tropical animals. The number of living organisms is enormous. Development takes place quickly, generation following generation in rapid succession. The butterfly *Danaus chrysippus* in the northern parts of its area of distribution is represented by one generation a year, but in the Philippines it requires only 23 days for complete development. Among mammals also development is accelerated. The widespread belief that puberty in man, as shown by the age at menarche, is reached earlier in southern latitudes holds only in a general and rather indirect way, there are many exceptions.

The number of species in the tropics is astonishing. South America has 4,560 species of Lepidoptera, while the whole of the Palaearctic region (Asia north of the Himalayas, Europe and North Africa) has only 716. The Brazilian states of Para and Amazonas have 1,117 species of birds, i.e., almost as many as the whole Palaearctic region (1,218). The number of individuals of a single species, however, is usually limited, of insects and spiders it is often easier to collect 100 different species than 100 individuals of one species. The absence of seasons causes reproduction to go on during the whole year, one may find at any time of the year eggs, larvae, pupae and fully developed animals.

Temperate Regions.—On the other hand, in regions where periodical changes of temperature give rise to seasons, animals are subjected to conditions varying from times of plenty to times of need. It is immaterial whether the changes be between summer and winter, or between rainy season and dry. Summer and the rainy season bring the most favourable conditions, winter and drought the least favourable. Animal life languishes under unfavourable conditions, lack of warmth in one place bringing about a state similar to lack of moisture in another. When, however, the bonds are loosed, the awakening of the animal world is often the more crowded owing to the simultaneous appearance of many species. Most species immediately set about reproduction, the chirping of crickets, the croaking of frogs, and particularly the songs of birds, together with the awakening of plant life, is in sharp, refreshing contrast to the desolation of winter and the dry season. In winter, or the dry season, many terrestrial animals cease their vital activities. Aestivation in time of drought is common among insects, spiders and snails; frogs and toads creep into holes in the earth or other hiding places, and remain there in a deathlike sleep. Crocodiles dig themselves into the mud of pools which are drying up, and rest beneath the hardened crust. This habit of sleeping through the dry season is also found among mammals, e.g., the armadillo (*Orycteropus*) in Africa. In winter, poikilothermal animals hibernate in a regular way; this may also occur in warm blooded animals, which undergo a drastic fall of temperature and a slowing-down of the rate of metabolism. Such are hedgehogs, bats, ground squirrels and marmots. Among birds, however, we find neither hibernation nor aestivation, many withdraw from the reach of unfavourable seasons by migrating. Many mammals also migrate as a result of seasonal changes of weather. It occurs among South American antelopes, subarctic reindeer and diverse birds. Among birds of tem-

perate regions, we may distinguish a general resident population which dwells the whole year in the same locality, migratory birds present only for the breeding season (summer visitors) or only in the nonbreeding season (winter visitors) or occurring on passage between their summer and winter habitats. According to the climate of the habitat the same species may be resident in one locality and migratory in another. Thus in England birds such as starlings and song thrushes remain throughout the winter, in central Europe they migrate. Some birds travel great distances, the summer and winter quarters of *Sterna paradisaea* are 17,700 km apart. The change from rainy season to dry causes migration, as in Africa.

The nature of the soil of a locality is important in determining the composition of its population. Among mammals the two-legged jumping animals require a hard substratum which offers a firm foothold. These are found in all the steppe regions of the earth. Such are jerboas, the jumping hare *Pedetes* and the kangaroo group of marsupials. Running animals, such as carnivores that go upon their toes, and ungulates, which place only the tips of the toes on the ground, thrive best on a hard soil with little friction. Ungulates living on sand—the desert antelope, *Gazella lodari*—on bog, as does the moose, or on snow, like the reindeer or caribou (fig. 10), have the surface of the hoof expanded to prevent sinking, they have three or four toes (pigs and tapirs), or two toes bearing elongated hooves, which can diverge widely. The toes of lizards that live on loose sand sometimes have fringes along the sides.

A DESERT COMMUNITY

The American desert in bloom, as painted for "Encyclopædia Britannica" by Walter A. Weber

Deserts are developed under the climatic influence of small annual rainfall (among other factors), the vegetation over wide areas being so reduced that bare soil appears between the individual plants, while the species, genera and families composing the flora are radically and characteristically modified by evolution toward adjustment to dry conditions. The associated animals are often equally characteristic. The deserts of the world accordingly present one of the major types of biotic formation.

When a desert has been in existence for a long period of time, as in south western North America, a rich and remarkable flora with an equally rich animal association may result. When the desert is more recently established, as on the coastal plain of Chile and Peru, vegetation and attendant animal life may be almost wholly lacking. This is the case also where there are large areas of moving sand, which vegetation is able to bring to a halt only when there is sufficient rainfall.

The variety of plant life in the United States desert becomes the more conspicuous when it bursts into bloom after rain, whether in spring or at another season. The desert vegetation then belies its reputation for grayness and dullness of tone, and presents the rich greens and bright flowers of the accompanying plate. The visitor to the Big Bend of western Texas or to the giant cactus region of Arizona who is so fortunate as to arrive a week after a rain will be charmed by the brilliant reds and yellows of the cactus blooms, and by the bright green fringe of the spiny ocotillo stems, with their flaming terminal flower spike.

The more abundant animals of the U. S. desert are often nocturnal, and there is a great variety of small and medium sized rodents, together with the long limbed and long eared hares. Even the smaller mammals, in most deserts, include a great variety of jumpers. Most notable of the larger mammals are only native to the intermontane deserts of North America, and found even under the most extreme desert conditions, is the prongbuck, the so called "antelope" of western America. One of the primary adjustments of desert herbivores to sparse vegetation is the development of great powers of locomotion. This is notably the case with the prongbuck. Noticeable also is the white hair marking of the buttocks of this animal, in which the coarse white hairs are erectile and are spread in a pallid fan that catches the sun and is distinctly conspicuous even at great distances. This is a most distinctive adaptation to open country and to life in gregarious herds. It apparently functions as a warning signal from herd to herd and as a recognition and herd integrating mark from individual to individual.

The development of especially large ears is to be seen in the kit fox (shown in the plate opposite) and this likewise is a characteristic of many desert mammals, reaching an astonishing extreme in such forms as the jack rabbit of southern Arizona or the fennec foxes of Africa and southwestern Asia.

FIG. 10—TOES OF FORE FOOT OF REINDEER (RANGIFER)

peratures, many withdraw from the reach of unfavourable seasons by migrating. Many mammals also migrate as a result of seasonal changes of weather. It occurs among South American antelopes, subarctic reindeer and diverse birds. Among birds of tem-

Soil—Of the chemical constituents of the soil calcium merits the first consideration. Animals which require much lime for building up their bodies thrive better on chalky ground than on soil poor in lime. Among mammals this is particularly noticeable in deer, which require lime for the annual renewal of their antlers. Roebuck in limestone regions have stronger antlers than those in sandstone districts. Further, the body weight of the roe deer is greater in limestone districts. In Württemberg the weight of the carcase of the roe deer in limestone regions exceeds 14 kg., but in districts with little lime in the soil (sandstone moorland) it is below 14 kg. The amount of lime in the soil and, therefore in the drinking water, affects mankind also, this shows itself particularly plainly in the teeth. The number of decayed teeth in school children is much higher in regions poor in chalk than in those rich in it. Snails are more numerous in limestone regions, both in species and in individuals, owing to the chemical composition of the soil and to the greater warmth of the calcium rich soil. Lime also reduces soil acidity and increases soil aeration.

Other animals require a large amount of salt in the soil and are widely distributed on sea coasts, inland, they are found only on salt ground, as at Stassfurt and in similar localities. This applies particularly to the small beetles (Staphylinidae, Carabidae) and other insects. Salt is sought after by mammals also, particularly by herbivores, places where it crops up are much resorted to by ruminants, and in primeval forests they have paths converging to them from all directions.

The Fauna of Forests—Large forests are found only in regions where during the summer vegetative season, a minimum temperature of 10° C prevails, a minimum rainfall of 50 cm. and an atmospheric humidity of more than 70% saturation. The dense covering of the tree tops hinders penetration of heat rays, evaporation of moisture and air currents. For this reason, temperature, humidity and air current vary much less in open country. The density of forests, moreover, varies greatly, all grades are found from the tall hot, impenetrable, dripping rain-forests of the tropics to the light pine forests near the tree limit on mountain slopes and in the subarctic

region. The peculiarities of forest animals are seen most plainly in the tropical rain forests, which form an immense zone round the earth at the equator, and include the Congo forest region the forests of southern Asia and the islands of that region and the selvas of the Amazon.

Orientation is possible only for short distances, eyes and organs of smell are not used, the sense of hearing is the most useful. Most gregarious forest animals, therefore, such as birds and monkeys, are noisy, in contrast to those of open country. The light is subdued and much reflected brilliant colours do not show up the value of protective coloration is lessened by the restriction of the outlook. Flying and running are hampered, the true forest birds are usually poor fliers, but are good at gliding and climbing. Some forest animals, such as elephants and large swine, are able to force their way through, others are small and slender, stand lower in front than behind, carry the head low and are able to squeeze through narrow places, e.g. forest antelopes (*Cephalophus*, *Tragelaphus*), forest deer (*Moschus*) and *Axis* (*Dasyprocta*). Many birds and mammals are equipped with sharp claws (woodpeckers, squirrels, marmosets), others have prehensile tails (many South American monkeys), the porcupine *Erethizon*, the anteater, various marsupials.

Chimbing animals in forest regions include also many reptiles and amphibians, such as the literally compressed tree Agamidae of the old world, and the tree iguanas of the new world, the long, slender tree snakes and numerous tree frogs. Panchromatic animals, such as parrots, primates, monkeys, arboreal marsupials, some have prehensile tails (many South American monkeys), the porcupine *Erethizon*, the anteater, various marsupials. Climbing animals in forest regions include also many reptiles and amphibians, such as the literally compressed tree Agamidae of the old world, and the tree iguanas of the new world, the long, slender tree snakes and numerous tree frogs. Panchromatic animals, such as parrots, primates, monkeys, arboreal marsupials, some have prehensile tails (many South American monkeys), the porcupine *Erethizon*, the anteater, various marsupials. Climbing animals in forest regions include also many reptiles and amphibians, such as the literally compressed tree Agamidae of the old world, and the tree iguanas of the new world, the long, slender tree snakes and numerous tree frogs. Panchromatic animals, such as parrots, primates, monkeys, arboreal marsupials, some have prehensile tails (many South American monkeys), the porcupine *Erethizon*, the anteater, various marsupials.

The more a forest departs from the extreme type of the tropical rain forest, the more the characteristic peculiarities of its inhabitants are effaced. In the forests of temperate regions the characteristics of the fauna are mostly determined by the nature of the forest. Coniferous forests have a different animal population from coniferous forests, while mixed forests have an intermediate type of population. In deciduous forests gastropods are represented by many species, in pine forests they are almost absent. Many forest insects are restricted in diet either to deciduous or to coniferous trees. Deciduous forests in Europe are inhabited by the black grouse (*Tetrao tetrix*), numerous songbirds and by the dormouse (*Muscardinus*). In the forests of mammals in North America the characteristic birds include the ruffed grouse (*Bonasa umbellus*), a great variety of thrushes and the small mammals include a variety of squirrels and deer mice (*Peromyscus*), and the cottontail rabbit (*Sylvilagus*). Coniferous forests in Europe are inhabited by the capercaillie (*Tetrao urogallus*), great black woodpecker (*Picus major*), nutcracker (*Nucifraga*), crossbill (*Loxia*), siskin (*Carduelis spinus*) and kinglet (*Regulus*). The corresponding forest in North America has related *Loxia* and *Regulus*, and a host of nesting birds, such as the wood warblers unknown in the old world. The characteristic mammals, like the moose, tend to exhibit circumpolar relations.

Fauna of Open Country—Open country is in every respect in contrast to forest regions. Forests are not found where moisture and warmth are insufficient, in such places only grass and shrubs are present. Such lack of moisture is often found in great plains, both elevated and low lying. But there are numerous grades of open country, from savannahs and steppes to predesert (shrub steppe), and desert. The gradations depend on the degree of precipitation, this is greatest in subarctic grasslands, in arid steppes it is confined to the rainy season, and in waterless deserts it may be absent for years. In the rainy season, such regions show very diverse appearance, but in the dry season they are much more alike. All have an absence of protective foliage, and, on this account, variations of temperature and humidity are great, and atmospheric currents are strong.

In general only animals that can endure a dry atmosphere are able to exist in open country, those requiring moisture in the air, such as gastropods and amphibians, are rare, though there may be a wealth of the water beetles. An enormous number of animals seek shelter in holes and burrows in the ground from storms, enemies and variations of temperature. Here we find ants and other brood-nursing Hymenoptera and termites. Among reptiles there are swift moving snakes, like the American racers (*Coluber*) or the African *Psammophis* as well as many burrowing types. Among mammals, rodents show the greatest number of burrowing forms, such as the marmots (*Marmota*), prairie dogs (*Citellus*), skunks (*Spermophilus*), rats, voles, hamsters (*Cricetus*), jerboas, porcupines, the South American tricomorphs (*Ctenomys*, *Dolichotis*, *Visiaca*), and rabbits (*Lepus*).

A NORTH AMERICAN TEMPERATE GRASSLAND COMMUNITY

As painted for 'Encyclopædia Britannica' by Walter A. Weber

The biotic formation or biome usually termed temperate grassland or steppe is pre eminently developed in North America, extending from Alberta to the Mexican plateau as a continuous north-south band, bordered by the semiarid scrub of the Rocky Mountain foothills on the west and by the forests of the eastern United States and Canada on the east. The western portion of this area, the great plains is covered by short grass sod, merging to the east into the higher mixed grassland of the United States savanna—the prairie.

That such grasslands in various parts of the world have had a long geological history is evidenced by the association with them of animals eminently adapted to the plains environment, and specifically adapted to feeding on grass, whether on the lush growth of spring or on the winter killed but nutritious dry stems and seed filled heads.

In western North America the transition to desert is gradual to the southwest and again between the high grass prairies and the eastern forests, which in the terdigrade in alternating grassy ridges and tree fringed river courses a. the Mississippi is approached from the west.

In North America the conspicuously dominant large grassland mammal was for ages the bison (In American English, the buffalo) *Bison bison*. The American bison had even more gigantic predecessors in the late Tertiary and in Pleistocene times. Bison lived great but variously fragmented herds, which merged for an obscure north-south and south-north seasonal migration. The food of these vast assemblages of herbivores was supplied by the sod forming low grasses of the "short grass plains," such as buffalo grass (*Bouteloua dactyloides*) and the blue grama (*Bouteloua gracilis*). The predominance of these grasses seems to be directly associated with the presence of the herbivorous herds, whose continuous grazing holds back the taller grasses.

The carnivores most evidently associated with the bison were the wolves and coyotes preying on the aged and crippled individuals and taking an occasional unguarded calf.

The scene on the plate opposite is idealized to represent the appearance of the "short grass plains" before the coming of the white man. The American Indians, after their advent to the plains, became the principal bison predator, but even after the acquisition of the horse, they quite evidently lived only on the surplus of the wild herds.

The near extermination of the bison as a species toward the end of the 19th century, and its preservation by the activity of a group of active and vocal conservationists are part of the history of the conquest of North America by the white man.

Open grasslands and large gregarious herbivorous mammals, with attendant ant-carnivores are correspondingly developed in Africa, Eurasia, South America and Australia.

cuniculus), they often live in flocks, communities, and underground, excavated areas (Armadillos - *Dasypus*), and burrows (*Orizotopus*), warts hogs (*Phacodermis*), and predatory mammals (e.g., the American badger) dig holes for themselves in open country. The birds are ground breeding forms, but others such as eagles which usually nest in trees occasionally breed on the ground in such regions. Others again (Sparrows) in such regions, where there is little cover, the coloration of the animals is frequently adapted to that of the surroundings, the less cover present the greater the degree of adaptation. This is found to the greatest degree in deserts, where the most varied kinds of animals have coloration similar to that of the ground. A few insects which have special protection in their hard cuticle (some Tenebrionidae), or which eject a poisonous fluid against attackers (the locust *Egypus gervini*), have a striking black coloration. Black is an oft seen desert colour.

Agile animals are particularly characteristic of open country. Here, as found running birds and cats, the swift, agile, desert fox (*Fox*) and larks. The solipeds and two-legged jumping animals are inhabitants of open country. Visual and olfactory organs assist orientation, as the outlook is wide and the winds carry scents. Animals of open country, in contrast to those of forests, make little noise. Gregarious animals are particularly common. The extreme grasslands are the richest game regions of the world. The North American prairies formerly harboured enormous herds of bison, the South African plains still swarm with herds of hoofed animals.

Plains where winter is the dry season and the summer covered with snow (this season differs in the two hemispheres). In the dry season the former offer food in dry grass and its seeds, which keeps life from dying out. In regions where the grass in winter is covered by snow, vegetation is less available as food and animals tend to hibernate or migrate. When the dry season is past and the first rains begin, life awakens suddenly, but where there is snow plants and animals awaken gradually at the end of the winter. All these peculiarities are most marked in desert regions with their extreme conditions of life, the scarcity of animal life and the sharp contrast, the frequency of protective coloration, the pale coloration of the animals are all direct effects of climate.

Fauna of Mountain Regions.—In mountain regions there is generally sufficient moisture for the growth of forests, but, with the decrease of temperature in proportion to increase of altitude, the forests are confined to a zone, higher or lower according to latitude. In the Colombian Andes the limit of trees is 3,200 m above sea level, in the Swiss Alps, on an average 1,800 m. The forest fauna extends to this limit above, and adjoining it from the lower limit of the region of snow, a characteristic alpine fauna is found. As the height above sea level increases, atmospheric pressure and temperature decrease. The low atmospheric pressure, the small quantity of oxygen in the air, causes an increase in the number of red blood corpuscles in homoiothermal animals. Plains dwelling mammals suffer from lack of oxygen if they ascend high ("mountain sickness"). Nevertheless, mammals are able to dwell at heights of more than 6,000 m, e.g., the rodent *Ochotona pallasi* at 6,125 m on Mt. Everest. More important is the decrease in temperature, and the shortening of the warmer season in alpine regions. For these reasons the number of species decreases rapidly with increasing altitude. In Switzerland up to 700 m there are 178 species of birds, up to 1,800 m 178 species (partly other kinds) in the alpine region (up to 2,700 m) 90 species, in the region of the snow only 8 species. The species of gastropods, insects and mammals show a similar decrease. The special conditions of temperature at ground level lessen, for small animals, the unfavourable climate of mountain regions. In consequence of the strength of the sun's rays, the surface layers of the ground, and the air in the tusssock

only warmed by the sun from time to time. Homoiothermal animals are more independent of temperature, but are very dependent on food to obtain it, they often migrate down towards the valleys in winter. Most truly alpine birds are nonmigratory, many truly alpine species are relatively scarce. Homoiothermal animals in high mountain areas are often larger than their relatives in the plains, e.g., the tree-creeper (*Certhia familiaris*) and the wood mouse (*Mus sylvaticus*) of the Swiss Alps. Many specifically mountain dwellers can not live in the plains, they are isolated in the mountain ranges by the surrounding lowland, and have been transformed into geographical races, e.g., the ibex (*Capra ibex*) of the Alps, Caucasus, Taurus mountains, Mt. Sinai and Abyssinia.

Fauna of Polar Regions.—Variation similar to that in the fauna of the lower slopes of mountains appears in regions approaching the north pole. Organisms in the arctic and in the antarctic regions are very different owing to the difference in the topography and climate. In arctic regions there is a short summer, with sunshine and high temperatures, which awakens plant and animal life, in the antarctic, although the winter is not quite so cold, the summer is cooler, and the sky is constantly overcast, and therefore little life develops on land and Arctic and the highest alpine regions have many species in common, which are absent in the intervening areas, such as the Alpine hare (*Lepus timidus*), the ptarmigan (*Lagopus mutus*), the gastropod *Acanthina harpa*, and some lepidopterans, which traversed the warmer intervening areas during the Glacial period. The number of arctic insects is not so great as might be expected. Diptera and Hymenoptera are most abundant, Orthoptera and Hemiptera are rare. Among Hymenoptera, bumblebees are relatively numerous and are strikingly large, thus having proportionately smaller surface to give off heat. The few species of gastropods are small. Amphibians and reptiles are found only in the southern portion and these species are the same as those ascending highest in mountain regions. Homoiothermal animals are characterized by adaptations for conservation of heat, they are sturdy, have short appendages (ears and tail) and a thick covering of fur or feathers. The white colour of so many polar birds and mammals is important in reducing heat radiation. Experiments have shown that the proportion of heat given off by light coloured and black guinea-pigs is as 100:124. Polar mammals do not hibernate, as the frozen ground provides no protection from temperatures below freezing point. The number of birds and mammals is small, apart from those which find their food in the sea. In eastern Greenland, among polar bears and seals, only seven kinds of mammals are found (the hare, lemming, musk ox, reindeer, ermine, arctic fox and wolf). In Spitzbergen, there are only two kinds, the reindeer and arctic fox. In the antarctic truly terrestrial animals are practically absent, all homoiotherms are confined to the continent.

Animals of Islands.—The characteristic peculiarities many island faunas have in common result chiefly from isolation. Animals of islands are originally derived from those of continents, and the sea forms a barrier preventing the influx of the parent species. This barrier, however, is not insuperable. In many cases land connections were formerly present. Such islands are termed "continental", in contrast to "oceanic" islands, which have arisen in the sea by volcanic agency, or as coral reefs, and were originally devoid of terrestrial animals. Isolation brings about differentiation of species, each form developing its peculiarities by intercrossing with the original stock. This process being continued, races are produced confined to certain localities. In all islands the length of the time of separation, and the degree of isolation, i.e., the distance from the mainland, is important, the longer and more complete the isolation, the greater the degree of differentiation of the species. Madagascar has long been isolated, forms of Ethiopian origin are here so greatly differentiated that, for example, all nonvolant mammals except a few later immigrants belong to endemic genera, and, usually, also to subfamilies and families not elsewhere. On the other hand, the British Isles, which have been separated only since the end of the Glacial period, have only one peculiar vertebrate (the red grouse).

In ancient oceanic islands, the number of endemic species increases with the distance from the mainland. While the Azores, in addition to endemic species, have many in common with Europe and Africa, most of the fauna of St. Helena is endemic. The distance of the Hawaiian Islands (more than 3,000 km from the mainland) has there are numerous genera, and among gastropods and birds, families also, which are not found elsewhere.

The isolation of oceanic islands by the sea implies selection in the fauna. Mammals, amphibians and freshwater fish are unable to overcome this obstacle, and are therefore absent. Reptiles can seldom reach such islands, but birds can do so much more frequently. Flying insects may be carried to them by winds, and some even reach them unsaid.

Terrestrial gastropods and wood-boring insects (e.g., weevils) reach them on driftwood.

Isolated regions offer shelter from rivals and enemies. Thus, in Tasmania, the carnivorous marsupials *Thylacynus* and *Sarcophilus* can hold their own, but on the Australian continent they succumb to the imported dingo. Loss of the power of flight, which often occurs in birds inhabiting islands, is connected with the absence of mammals, in the Galapagos Islands there is a flightless cormorant (*Phalacrocorax*), in New Zealand the kiwi (*Apteryx*). On other islands, flightless birds have become extinct in historical times, as in Mauritius. The large

size of the birds found on islands may be connected with the loss of flying powers, the limit of size imposed by flight disappeared when this was abandoned. On the other hand, we frequently find dwarf varieties of mammals on islands, on the islands of the Red sea *Gazella arabica* does not exceed a third the normal weight of the species.

Some of the peculiarities of animals of islands are explained by the climate. On small islands feeble fliers are in danger of being carried out to sea by strong winds. For this reason most insects on the Polynesian islands take shelter from wind, in the East Frisian island few flying insects are found. Animals that feed on these insects (flycatchers, swallows, small bats, etc.) are also absent. On the storm swept islands of the subantarctic, numerous insects have vestigial wings (of eight species of flies in Kerguelen one only has normal wings). An evolutionary superiority of continental animals over the endemic forms of islands is often conspicuous. Extinctions of island forms have frequently resulted from the introduction of domestic animals by man, as in the case of the dodo and its associates, which appear to have been destroyed by pigs, or from the accidental introduction of continental forms, as is notably illustrated in the decline of the native insect fauna of Hawaii and in the effects of the recent introduction of an exotic land snail in the Marianas Islands.

DISTRIBUTION OF PLANTS. see PLANTS AND PLANT SCIENCE Plant Ecology

DISTRIBUTION OF TERMS In logic a term is said to be distributed in a proposition when explicit reference is made to its whole extent or extension. Otherwise (that is, not only when reference is made explicitly to a part only of the extension of the term, but when explicit reference is simply not made to its whole extension) it is said to be undistributed. Thus, in a proposition of the form *No S is P* both the subject and the predicate are distributed. In the form *Some S is P*, neither *S* nor *P* is distributed. In *All S is P*, *S* is distributed, but *P* is not. Lastly, in *Some S is not P*, *S* is not distributed, but *P* is. Briefly, only universal propositions distribute the subject term (*S*), and only negative propositions distribute their predicate (*P*). Naturally, singular terms (including proper names used as singular terms) are always distributed, for they only refer to one object, and can not refer to less. The importance of the distribution of terms arises from the fact that it is a principle of formal inference that no term may be distributed in this conclusion unless it was distributed in the premises. That is why, e.g. *All S is P* can only be converted into *Some P is S* (not into *All P is S*), and *Some S is not P* can not be converted at all.

DISTRIBUTIVE LAW, in algebra the law which asserts that $a(b+c+d) = ab+ac+ad$, one of two factors (*a*) being distributed, as it were, among the parts (*b, c* and *d*) of the other factor ($b+c+d$). Stated in words, the result of first adding several numbers and then multiplying the sum by another number is the same as the result of first multiplying each of the several numbers separately by the other number and then adding the products. For example, $2(5+3) = 2 \times 8 = 16$, and $2 \times 5 + 2 \times 3 = 10 + 6 = 16$. The law is equally valid for negative, fractional, irrational, and complex numbers.

DISTRIBUTOR, in electrical engineering, a form of switch, generally rotary, arranged so that it transmits successive electrical impulses to definite points in a given order (see MAGNETO, HIGH TENSION).

DISTRICT, a word denoting in its more general sense, a tract or extent of a country, town, etc., marked off for administrative or other purposes, or having some special and distinguishing characteristics (see LOCAL GOVERNMENT, etc.). In mediaeval Latin the word *districtus* is defined by Du Cange as *Territorium feudis, seu tractus, in quo Domini vassallos et tenentes suos distringere potest*, and as *iustitia exercendae in eo tractus facultas*. It was also used of the territory over which the feudal lord exercised his jurisdiction generally. In British India the word is used to represent the *sillah*, an administrative subdivision of a province

or presidency.

In the United States of America the word has many administrative, judicial and other applications. In South Carolina it was used instead of "county" for the chief division of the state other than in the coast region. In the Virginias, Tennessee, Georgia, Kentucky and Maryland it answers to "township" or precinct, elsewhere the principal subdivision of a county. It is used for an electoral "division," each state being divided into congressional and state legislative districts, and also for a political subdivision either of an unorganized or an organized territory.

DISTRICT OF COLUMBIA see WASHINGTON, D C

DISTYLE, in architecture, a portico of two columns, usually between antae (*q v*) and called "distyle in antis," or a building with such a portico in front, e.g., so called treasuries at Delphi.

DITA BARK, the bark of a fruit tree (*Alstonia scholaris*) growing in the Philippines and elsewhere. It has had considerable local reputation as an antimalarial but later work has shown it to be of little or no value as such.

DITHMARSCHEN or **DITMARSH** (in the oldest form of the name *Thuatmarsgah*, Dietmar's Gau), a territory between the Eider, the Elbe and the North sea, forming the western part of the old duchy of Holstein. It contains about 550sq m, half of which consists of good pasture land, preserved from mroads of the sea by banks and dams, the other half being mostly waste. The district was subjugated and Christianized by Charlemagne, and ranked as a separate Gau, probably included in the countship of Stade. Ultimately the archbishops of Bremen claimed supremacy over the land, but the inhabitants, who had developed and consolidated a systematic organism for self government, made obstinate resistance, and rather attached themselves to the bishop of Schleswig. Dithmarsh continued part of the Danish dominions till the disastrous battle of Bornhöved in 1227, when its former independence was regained. The claims of the archbishop of Bremen were now so far recognized that he exercised the royal rights of *Hoerbann* and *Blutbann*, and was represented first by a single *advocatus*, or *Vogt*, and afterwards by one for each of the five *Dofits*, or marks, into which the land was divided after the establishment of Meldorf. The community was governed by a *Landrath* of 48 elective consuls, being 12 from each of the four marks. In 1319 and 1404 the inhabitants defeated the invasions of the Holstein nobles, and though in 1474 the land was nominally incorporated with the duchy by the emperor Frederick III, the attempt of the Danish king Hans and the duke of Gottorp to enforce the decree in 1500 resulted only in their complete rout in the marshes of the Dussend Duwels Warf. During the early part of the following century Dithmarsh was the scene of violent religious conflict, and, thus weakened, it was obliged in 1559 to submit to partition among its three conquerors—King Frederick II of Denmark and Dukes John and Adolphus. A new division took place on Duke John's death in 1581, by which Frederick obtained South Dithmarsh, with his chief town of Meldorf, and Adolphus obtained North Dithmarsh, with his chief town of Heide, and this arrangement continued till 1773, when all the Gottorp possessions were incorporated with the Danish Crown.

R. Dahlmanns Vorlesungen (1873).

DITHYRAMBIC POETRY, the description of poetry in which the character of the dithyramb is preserved. It remains quite uncertain what the derivation or even the primitive meaning of the Greek word *δithyrambos* is. It was, however, connected from earliest times with the choral worship of Dionysus. The earliest dithyrambic poetry was probably improvised by priests of Dionysus at solemn feasts and expressed, in disordered numbers, the excitement and frenzy felt by the worshippers. The dithyramb was traditionally first practised in Naxos, it spread to other islands, to Boeotia and finally to Athens. Arion is said to have introduced it at Corinth, and to have allied it to the worship of Pan. It was thus "merged," as Professor Gilbert Murray says, "into the Satyr choir of wild mountain-goats" out of which sprang the earliest form of tragedy. It flourished in Athens until

after the age of Aristotle. So far as we can distinguish the form of the ancient Greek dithyramb it must have been a kind of irregular wild poetry, not divided into strophes or constructed with any evolution of the theme. It was accompanied on some occasions by dances on others by the lyre. Pindar, in whose hands the ode took such magnificent completeness, is said to have been trained in the elements of dithyrambic poetry by Iphias of Hermione. In the opinion of antiquity pure dithyrambic poetry reached its climax in a lost poem *The Cyclops*, by Philoxenus of Cythera, a poet of the 5th century B.C.

In modern literature although the adjective "dithyrambic" is often used to describe in enthusiastic movement in lyric language and particularly in the ode, pure dithyrambs have been extremely rare. The *Seuco e Isaura* of Francesco Redi (1626-88), which was translated from the Italian, with admirable skill by Leigh Hunt, is a piece of genuine dithyrambic poetry. *Alexander's Feast* (1691), by John Dryden, is the best example in English. But perhaps more remarkable, and more genuinely dithyrambic than either, are the astonishing improvisations of Karl Mikul Bellman (1731-95) whose Bacchic songs form one of the most remarkable bodies of lyrical poetry in the literature of Sweden.

DITTERSBACH, a town of Germany, in the Prussian province of Silesia, 3 mi. by rail S.E. from Waldenburg and 50 mi. S.W. from Breslau. It has coal mines, bleachworks and match, chemical and benzole works. Population (1933) 15,392.

DITTERSDORF, KARL DITTER VON (1759-1799), Austrian composer and violinist, was born in Vienna on Nov. 2, 1759, his father's name being Ditters. He took the name of Dittersdorf on his ennoblement in 1773. The boy Ditters was a brilliant violinist and attracted the attention of Prince Joseph Frederick of Hildburghausen (1702-87), who gave the boy, then 11 years old, a place in his private orchestra—the first of the kind established in Vienna. Later he obtained a place in the Vienna opera, and subsequently in 1761 he accompanied Christoph Gluck to Italy where his violin playing won him great renown. He became conductor of the orchestra of the bishop of Grosswarden, a Hungarian magnate, at Piestburg. He set up a private stage in the episcopal palace, and wrote for it his first "opera buffa," *Amore in musica*. His first oratorio, *Isacco figura del Redentore*, was also written during that time, but the scandal of performances of light opera by the bishop's company, even on fast days and during Advent, outweighed this pious effort, the empress Maria Theresa sharply called the bishop to order, and he, in a huff, dismissed his orchestra (1769).

After a short interlude, Ditters was again in the service of an ecclesiastical patron, Count von Schafgotsch, prince bishop of Breslau, at his estate of Johannsburg in Silesia. At Johannsburg Ditters also produced a comic opera, *Il Viaggiatore americano*, and in oratorio *Davide*. The title role of *Davide* was taken by Signora Nicolini, whom Ditters married. In 1773 his oratorio *Ester* was produced in Vienna. After the peace of Teschen (1779) he again became conductor of the reconstituted orchestra of the bishop of Breslau. From this time forward his output was enormous. In 1780 ten months sufficed for the production of his *Giobbe* ("Job") and four operas, three of which *Doktor und Apotheker* (1786), *Das Rotkapchen* (1788) and *Hieronymus Knacker* (1789) had a great success. But when the bishop died in 1795, his successor dismissed the composer with a small money gift.

Poor and broken in health, he accepted the asylum offered to him by Ignaz Freiherr von Stillfried, on his estate near Neuhaus in Bohemia, where he continued to write operas, symphonies and symfonette pieces. He died on Oct. 1, 1799, leaving "God's reward" for whoever should save his family from starvation. On his deathbed he dictated to his son his *Self-study* *op. 100*.

While in the work of Luigi Boccherini there are traces of the influence of Franz Joseph Haydn as a force tending to disintegrate the symphonies, suite forms of instrumental music in Dittersdorf, and the other hand the popular conception of the modern symphony and orchestral style is seen.

Some of Dittersdorf's symphonies on the *Melancholische* of Ossi-

were republished in 1899 (ed. J. Liebeckind, Leipzig) the century of his death. The end of the representation of the conversion of the Lycian peasants into frogs is prophetically and ridiculously Wagnerian in its ingenious expansion of rhythm and eminently expert orchestration.

DICTIONARY, *Schönbibliographie*, published at Leipzig 1801 (English trans. by A. D. Coleidge 1869), an attack in the *Revue musicale* vol. 11, p. 7-7, the article "Dictionnaire" in Grove's *Dictionary of Music and Musicians*, K. Kall *Dictionnaire* (1900), with bibliography, and L. Rindler *Karl von Dittersdorf als Opernkomponist* (1911).

DITTO, that which has been said before, the same thing (from the Lat. *dictum* "something said," Ital. *detto*, "aforesaid"), frequently abbreviated into "do."

DIU, an island and town of India belonging to Portugal at the southern extremity of the peninsula of Kathiawar. The district (area 14 sq. mi.), which includes the village of Goah on the mainland and the fortress of Simbor 5 mi. W., is subject to the governor-general of Goa. Pop. of the island (1940) 19,731. The anchorage is protected from the sea, but the depth of water is only about two fathoms. The channel between island and mainland is navigable only by small craft. The town is surrounded by a wall with towers at regular intervals.

Many of the inhabitants become Banyan merchants of the east coast of Africa and Arabia. Industries which were established include mining salt, fishing and distillation of native spirits from the palm. The trade of the town, however, decayed.

There are remains of several fine ancient buildings. The cathedral of St. Matriz, dating from 1601, was formerly a Jesuit college. The Portuguese under treaty with Bahadur Shah of Gujarat, built a fort there in 1535, but were besieged in 1538 and 1545. The second siege, the subject of an epic by Jeronymo Corte Real (*q.v.*) is one of the most famous in Indo-Portuguese history.

DIURETICS are drugs which produce an increased flow of urine. They are used for (1) the removal of excess water and salt from the body, thus relieving or preventing oedema such as may result from circulatory and nutritional disorders, (2) the hastening of the excretion of ingested poisons, (3) the removal of accumulated metabolic products, and (4) the dilution of urine in order to prevent precipitation of drugs in the kidney tubules (see SULFONAMIDES). In general, diuretics act either by increasing the filtration through the glomeruli or by decreasing the absorption from the tubules (see URINARY SYSTEM). The first group includes drugs which alter the osmotic pressure or electrolyte balance of the plasma, such as the saline diuretics, urea and intravenous sucrose, and drugs such as digitalis and strophanthin which improve the circulation by strengthening the heart. Drugs which decrease the tubular reabsorption include the mercurial diuretics such as mersalyl (salyrgan) and merbaphen (novasurol) and probably also the xanthine diuretics (theobromine, theophylline and caffeine). (F. L. A.)

DIURNAL MOTION, the apparent motion of the heavens from east to west resulting from the earth's rotation on its axis from west to east. The axis of this apparent motion passes through the celestial poles (coincident in direction with the earth's axis) so that the stars appear to describe circles around the pole star.

DIURNAL VARIATION, the small daily change in value of the magnetic quantities, dip, declination and the horizontal component of the earth's magnetic force, also the daily changes in meteorological quantities, such as temperature, pressure, cloudiness, etc. (See TERRESTRIAL MAGNETISM.)

DIUSHAMBE (now STALINABAD), a small town in Turkistan, capital of the Tadzhik S.S.R., situated south of the Hissar mountains but north of the town of Hissar, on the Dushambe river, a tributary of the K. Irtys river which flows into the Aral Sea. Pop. (1939) 82,540. It is the centre of a fertile loess area producing grains (including rice), cotton, melons, grapes, apricots and other fruits. The town itself is built on a low hill and its streets and gardens and water tank are shaded by poplars. Formerly of little importance, for its main link with the U.S.S.R. was a caravan route to Samarkand. Since 1924 developed rapidly after its connection by rail with Tashkent (1924) and the establishment of air communication with Tashkent and Kharov.

It is also a base for the All Union Academy of Science

DIVAN, Persian word, probably from Armenian, meaning a "countinghouse, bureau, tribunal", thence on one side, the "account books and registers" of such an office, and on another, the "room where the office or tribunal sits", thence again, from "account book, register," a "book containing the poems of an author," arranged in a definite order (alphabetical according to the rhyme words), perhaps because of the saying, "Poetry is the register (*divan*) of the Arabs", and from "bureau, tribunal," "a long seat, formed of a mattress laid against the side of the room, upon the floor or upon a raised structure or frame, with cushions to lean against" (E. W. Lane, *Arabic English Lexicon*, p. 930 *et seq.*). All these meanings existed and exist, especially "bureau, tribunal," "book of poems" and "seat", but the order of derivation may have been slightly different. The word first appears under the caliphate of Omar (A.D. 634-644). Later, as the state became more complicated the term was extended over all the government bureaus. The divan of the Sublime Porte was for long the council of the empire presided over by the grand vizier. (See DEWAN, ARABIC LITERATURE, and A. von Kremer, *Culturegeschichte des Orients unter den Chalifen*, vol. 1, 64, 198 (Vienna, 1875).)

DIVER, a name applied to many birds, but properly restricted to the family Gaviidae, containing the single genus *Gavia*. They are sea birds, strong swimmers, and feed mainly on fish. Their legs are set far back on the body, so that they cannot walk more than a few steps at a time, sometimes they progress on land by bounds. They fly well when once on the wing. The red-throated diver (*G. stellata*) has a patch of bay on the throat in summer dress, replaced by black in the striped black throated diver (*G. arctica*). The Pacific loon (*G. pacifica*) resembles the black throated diver. The yellow billed loon (*G. adamsi*) breeds in Arctic America from the Siberian coast to the Mackenzie delta. The genus and family constitute the order Gaviiformes.

The largest form is the great northern diver (*G. immer*) which has a black back, marked with white spots, a black head and neck, and two semi-collars of black and white vertical stripes. These birds inhabit the Arctic seas of both new and old worlds. They breed in the Hebrides, Scandinavia, Canada, Iceland and other suitable places in the north. The American form is usually called loon (*G. v.*). There is a remarkable mutual courtship, in which the birds may run erect over the surface of the water (see J. S. Huxley, *Journ. Linn. Soc.*, 1923).

DIVERS, EDWARD (1837-1912), English chemist, was born in London on Nov. 27, 1837. He was educated at the City of London school and the Royal College of Chemistry and then studied medicine at Queen's college, Galway where he also acted as assistant and demonstrator. Between 1853 and 1873 he held a number of posts at the medical schools of several London hospitals where he lectured on materia medica, on medical jurisprudence, and on physics and chemistry. In 1873 he accepted the post of professor of chemistry to the Imperial Government of Japan and stayed in Japan until he retired in 1899. Divers supervised the building and equipment of his own laboratories at the newly built engineering college. In 1886 the college was incorporated in the newly organized imperial university and Divers was transferred to the college of science of that university. After his retirement he lived in London, where he died on April 8, 1912.

His early work in Japan included an examination of Japanese minerals, which led to some fruitful work on tellurium and selenium. This was followed by work on the compounds of nitrogen and sulphur and on the composition of Japanese bird lime, the manufacture of calomel in Japan and Japanese meteorites and springs.

DIVERS AND DIVING APPARATUS The earliest reference to the practice of diving occurs in the *Iliad*, 16, 745-750 where Patroclus compares the fall of Hector's chariot to the action of a diver diving for oysters. Thucydides mentions the employment of divers during the siege of Syracuse to saw down the barriers which had been constructed below the surface of the water with the object of obstructing and damaging any Grecian war vessels which might attempt to enter the harbour. At the

siege of Tyre, divers were ordered by Alexander the Great to impede or destroy the submarine defences of the besieged as they were erected. Lavy records that in the reign of Perseus considerable treasure was recovered by divers from the sea. By a law of the Rhodians, their divers were allowed a proportion of the value recovered.

Early Diving Appliances—The earliest mention of any appliance for assisting divers is by Aristotle, who says that divers were sometimes provided with instruments for drawing air from above the water and thus they were able to remain a long time under the sea (*De Part. Anim.* 2, 16), and also that divers breathed by letting down a metallic vessel which did not get filled with water but contained the air within it (*Problem.* 32, 5). It is also recorded that Alexander the Great made a descent into the sea in a machine called a *Colymba*, which had the power of keeping a man dry and at the same time of admitting light. Pliny also speaks of divers engaged in the strategy of ancient warfare, who drew air through a tube, one end of which they carried in their mouths, whilst the other end was made to float on the surface of the water. Roger Bacon in 1240, too, is supposed to have invented a contrivance for enabling men to work under water, and in Vegetius's *De Re Militari* (editions of 1511 and 1532, the latter in the British Museum) is an engraving representing a diver wearing a tight fitting helmet to which is attached a long leather pipe leading to the surface where its open end is kept afloat by means of a bladder.

Repton invented "water armour" in the year 1617, but when tried it was found to be useless. G. A. Borelli in the year 1679 invented an apparatus which enabled persons to go to a certain depth. It embodied means for altering the specific gravity of the diver, but was not practical. John Lethbridge, a Devonshire man, in the year 1715 contrived "a watertight leather case for enclosing the person." This leather case held about half a hoghead of air, and was so adapted as to give free play to arms and legs, so that the wearer could walk on the sea bottom, examine a sunken vessel and save her cargo, returning to the surface when his supply of air was getting exhausted. It is said that Lethbridge made a considerable fortune by his invention. The next contrivance worthy of mention and most nearly resembling the modern diving-dress was an apparatus invented by Kleingert, of Breslau, in 1798. This consisted of an egg ended metallic cylinder enveloping the head and the body to the hips. The diver was encased first of all in a leather jacket having tight fitting arms, and in leather drawers with tight-fitting legs. To these the cylinder was fastened in such a way as to render the whole equipment airtight. The air supply was drawn through a pipe which was connected with the mouth of the diver by an ivory mouthpiece, the surface end being held above water after the manner mentioned in Vegetius, viz by means of a floating bladder attached to it.

In 1819, Augustus Siebe invented his "open" diving dress worked in conjunction with an air force pump. The dress consisted of a metal helmet formed with a shoulder-plate attached to a jacket of waterproof leather. The helmet was fitted with an air inlet valve to which one end of a flexible tube was attached, the other end being connected to the air pump. The air, which kept the water down below the diver's chin, found its outlet at the edge of the jacket, exactly as it does in the case of the diving bell. Excellent work was accomplished with this dress—work which could not have been attempted before its introduction—but it was still far from perfect. It was absolutely necessary for the diver to

maintain an upright or but very slightly stooping position whilst under water, if he stumbled and fell, the water filled his dress, and, unless brought quickly to the surface, he was in danger of being drowned. To overcome this and other defects, Siebe carried out a great many experiments, extending over several years, which culminated, in the year 1830, in the introduction of his "close" dress in combination with a helmet fitted with air inlet and regulating outlet valves. Though, of course, many great improvements have been introduced since Siebe's death, in 1872, the fact remains that his principle is in universal use to this day. The submarine work which it has been instrumental in accomplishing is incalculable.

Modern Apparatus—A set of ordinary modern diving apparatus consists essentially of seven parts, viz.—(a) An air pump, (b) an incompressible helmet with brassplate, or corselet, (c) a compressible, or flexible, waterproof diving dress, (d) a length of flexible non collapsible air tube, with metal couplings joining it to pump and helmet, (e) a pair of weighted boots, (f) a pair of lead weights for breast and back, (g) a life line. Most apparatus is fitted with a telephone, and submarine lamps are also largely used.

Helmet (figs 1, 2 and 3)—The helmet proper is separate from the corselet, and is secured to the latter by segmental neck rings which are provided on both these parts, enabling them to be connected together by one eighth of a turn, a catch on the back of the helmet preventing any chance of unscrewing. The helmet and corselet are usually made of highly planished tinned copper, the valves and other fittings being of gun metal. The helmet is provided with a non-return air inlet valve to which the air supply pipe is attached. This valve allows air to pass from the pump to the helmet, but not in the reverse direction. A regulating air outlet valve fitted to the helmet enables the diver to control the amount of air in the dress, and hence his buoyancy. By screwing up the valve, he retains the air in the dress, and so maintains or increases his buoyancy, by unscrewing it he allows the air to escape, thus causing the dress to become deflated, with a consequent loss of buoyancy. On reaching the bottom and starting work, the diver will adjust his valve so as to maintain himself comfortably in equilibrium, altering the adjustment only when he wishes to ascend, that is, of course, assuming, as should be the case, that air is pumped to him at a uniform rate. Thick plate glass windows are fitted to the helmet. The front window is detachable from the helmet, usually by unscrewing, though some helmets are fitted with hinged windows similar to those used for ships' scuttles.

Dress (fig 4)—The diving dress is a combination suit which is made of two layers of tanned cloth with pure rubber between, and which envelops the whole body from foot to neck, the sleeves being fitted with vulcanized rubber cuffs which make a watertight joint round the diver's wrists. The dress is also fitted with a vulcanized rubber collar, which is secured to the corselet, or brassplate, of the helmet in such a manner as to render all watertight.

Air Pipe—The diver's air pipe is flexible and non-collapsible. At the ends are fitted metal couplings for securing the pipe to the pump and helmet respectively.

Boots—To maintain himself in an upright position under water, the diver wears heavily weighted boots (about 32 lb the pair).

Weights—Two lead weights, 40 lb. each, one on the back and one on the chest, ensure the diver's equilibrium under water.

Life-line—The diver's life line is for use in case of emergency, for hauling the diver to the surface, and also for making signals, the diver and his attendant having a pre-arranged code in which varying numbers of pulls or jerks on the life line have definite

meanings. When the telephone is provided, the telephone wires are embedded in the life-line.

Diver's Telephone (fig 5)—This most useful instrument was introduced by Siebe, Gorman & Co and is used to day through out the British and many other navies. Means are provided whereby the attendant at the surface can converse with No. 1 or with No. 2 diver, or with both together. He can also put No. 1 diver into communication with No. 2, himself hearing their conversation. The telephone wires are embedded in the life line,

BY COURTESY OF SIEBE, GORMAN & CO LTD

FIG 5.—TELEPHONE APPARATUS WHICH ENABLES DIVERS TO CONVERSE WITH ATTENDANTS AND ONE ANOTHER

which has metal connections at each end for attaching to helmet and battery box. The diver's telephone receiver is situated generally in the crown of the helmet, and the transmitter between the front glass and one of the side glasses. The diver can ring a bell or buzzer at the surface by pressing with his chin a contact-piece situated inside the helmet.

Submarine Electric Lamps

(fig 6)—Very many forms of submarine lamps are available. Of these, the most widely used are those which incorporate incandescent electric bulbs, ranging in candle-power from 5,000 down to about 50, the former being supplied with current from the surface, the latter being self-contained with accumulator batteries in a watertight case.

Air Pumps—Diver's air pumps are of various patterns, depending principally upon the depth of water in which work is being carried out, since the greater the depth of water the greater the quantity of air required by the diver. The pumps are of the reciprocating type and are mostly manually operated. Fig. 7 shows the Siebe Gorman two cylinder double acting pump (removed from its tank chest) adopted by the British Admiralty. Pressure gauges are provided which indicate the pressure of air which the pump is supplying, and the depth at which the diver is working. The cylinders are water jacketed to ensure a supply of cool air to the diver.

Air Compressors driven by electric motors, oil and steam engines are sometimes employed. In these cases the air is delivered into steel reservoirs, the divers'

air pipes being connected to an air control panel which receives its air from the reservoir, so that in case of a breakdown of the motive power, a reserve of air sufficient to bring the diver safely to the surface is assured. A typical machine of this description is shown in fig 8. In the pearl and sponge fisheries the small boats from which the divers work are sometimes propelled by oil engines which also drive the air compressors.

The type of air pumping apparatus employed varies with the depth of water and the conditions under which the diving operations are conducted. Examples of manually operated and power-driven pumps are shown.

The Diver's Air Supply—The diver's air supply must be adequate both in volume and pressure—the volume sufficient to ensure proper ventilation of the helmet, and the pressure fully equal to that which corresponds to the depth of water at which the diver may be working. In fresh air, there is only 0.3% of carbon dioxide, and, at ordinary atmospheric pressure, no ill effects are felt

until 3% of the gas is present. As a diver descends, the pressure is increased and the effect of a small percentage of carbon dioxide in his helmet becomes greater.

J S Haldane, who conducted deep diving experiments for the British Admiralty, found from a large number of analyses of air issuing from the diver's helmet, that 15 cu ft of air per minute would be needed to keep the percentage of carbon dioxide at a safe level. This volume of air is required at all depths, so that the actual quantities required at different depths down to 231 ft are as follows —

Depth in fathoms	Depth in feet	Pressure per sq in above atmospheric pressure, in lb	Quantity of air at atmospheric pressure required per min by the diver cu ft
0	0		15
5½	33	14.7	3.0

38½	231	94.0	11.0
39½	231	102.8	12.0

Effects of Air Pressure on the Diver—When a diver descends into the sea, the extra air pressure to which he is subjected is instantly transmitted to the whole inside of his body. At great depths his blood vessels and tissues become saturated with nitrogen. It should be remembered that a gas in contact with a liquid on which it has no chemical action is absorbed by the liquid in amounts proportional to the pressure of the gas at the time. In the lungs we have the blood practically in contact with the air, which consists of three important gases—oxygen, nitrogen and carbon dioxide. Of these, the nitrogen alone can remain and accumulate in the blood, the oxygen is used up by the tissues, and the breathing prevents the pressure of carbon dioxide from in-

FIG. 7.—MANUALLY OPERATED 2 CYLINDER DOUBLE ACTING DIVERS AIR PUMP SHOWING VALVES AND AIR DISTRIBUTING ARRANGEMENT FOR ONE OR TWO DIVERS

creasing, so that the only gas which accumulates in abnormal quantity in the blood when the diver is under pressure is the nitrogen.

When gas is forced into a soda water bottle under pressure, the water appears to be unchanged so long as the pressure is kept up, but the moment the pressure is reduced, by the removal of the

cock, we see the gas come bubbling off the liquid. J S Haldane has applied the analogy to diving. He says: "The diver is the soda water bottle, and his blood the fluid in the bottle. As the diver descends, nitrogen under pressure is forced into contact with his blood, which takes up the nitrogen from the air. So long as he stays below under that pressure, his blood appears to be unaltered, when however, he rises, the excess of nitrogen that the blood has taken up begins slowly to bubble off, if the blood were as fluid as water, it would come off as rapidly as from the soda water. Fortunately for the diver, the blood is a thickish, albuminous fluid, in which bubbles do not readily form, and, as far as we can see, it can retain about twice the amount in solution that water can keep at any given pressure. Every diver knows that it is quite safe to come up from a depth of five or six fathoms to the surface as

Up to Feet	Fathoms	Pressure Lbs per sq in	Time under water from surface to beginning of ascent	Stoppages in minutes at different depths, feet					Total time for ascent in minutes

quickly as he likes, the reason for this will now be easily understood, since at such a depth the blood has only twice as much nitrogen in it as it has on the surface and therefore, bubbles are unlikely to form. If, however, the diver has been for any considerable time at, say 180 ft., and then comes up too quickly it is almost certain that bubbles will form and cause serious symptoms, such as paralysis of the legs (diver's palsy), severe pains in the

BY COURTESY OF SIEBE GORMAN AND CO. LTD.

FIG 8—OIL ENGINE DRIVEN AIR COMPRESSING SET WITH STEEL AIR RECEIVER FOR SUPPLYING AIR TO 4 DIVERS SIMULTANEOUSLY. The compressed air after being cooled is delivered into air receiver whence it passes to four control valves to which are connected divers air tubes.

joints and muscles etc. Not only is the air taken up by the blood but the tissues of the body also get saturated with it. In the case of the blood, the saturation is very quick, it is probable, indeed, that the blood leaving the lungs is always saturated to the existing pressure, but the tissues take up the gas at a much slower rate—a rate which depends on the blood supply. Where this is good, as in the brain and spinal cord, the saturation is quick, but in the fibrous tissues about the joints, etc., saturation is very slow. Those tissues which are saturated quickly also give up their surplus nitrogen quickly, and those which saturate slowly also desaturate slowly.

In ascending, the diver is decompressing himself, and it is this gradual decompression that is the most important factor in the prevention of accidents from the formation of bubbles of nitrogen. The dangers are to be avoided by working to the following schedule drawn up by Prof. Haldane, during which there is but little chance of the diver getting dangerously saturated with nitrogen. It is important that the diver descend as fast as his air supply will allow him, for every minute spent in descending is time lost, since his body is becoming saturated.

Compressed Air Illness.—Although the rules laid down are circulated completely to prevent compressed air illness, cases do sometimes occur, owing to accidents or mistakes, where the diver comes up too quickly from deep water. In such cases, whether the diver has already shown symptoms of compressed air illness or

BY COURTESY OF SIEBE GORMAN AND CO. LTD.

FIG 9—RECOMPRESSION CHAMBER FOR TREATMENT OF CASES OF COMPRESSED AIR SICKNESS DUE TO TOO RAPID ASCENT FROM DEEP WATER.

not, he should be sent down again without delay to the depth at which he has been working, and kept there for five minutes, after which he can start to come up again at the following rates:—

While the pressure on the pump gauge is—	Pressure should be allowed to fall at a rate not faster than—
Over 30 lb	1 lb in one minute
Between 30 lb and 15 lb	1 " " two minutes
15 " " 10 "	1 " " three "
10 " " 0 "	1 " " five "

On some deep diving operations, however, a Siebe Gorman Re-

compression chamber, as fig. 9, is provided, the use of which is a much better and more comfortable method of treatment than sending the diver into deep water again. This chamber is of steel, provided with a bench on which the diver can sit or lie, electric light, telephone, etc. Windows are provided through which the diver can be watched during the process of decompression, a small hand air lock attached to the chamber allows refreshments, etc., to be passed into him. It is usually found sufficient to raise the pressure in the chamber to 30 lb, but it should never exceed 45 lb. As soon as the diver is relieved of any symptoms, the pressure is allowed to fall at the following rates:—

When the pressure in the chamber is—	Pressure may be allowed to fall at a rate not faster than—
Between 45 lb and 30 lb	1 lb in three minutes
30 " " 15 "	1 " " five "
Below 15 "	1 " " eight "

Helium and Oxygen for Deep Sea Diving.—Some years ago the proposal was made by Prof. Elhu Thomson, F.R.S., of Swimpson, Miss., U.S.A., to use helium in place of nitrogen in the atmosphere supplied to divers engaged in deep sea work, and the practical utility of this suggestion has been demonstrated recently by experiments conducted at the Government Bureau of Mines, U.S.A. Helium has a solubility in water nearly 40% less than nitrogen, therefore, during exposure to compressed air, nearly 40% less gas will be dissolved in the watery part of the body. The rate of diffusion of helium is 2.64 times that of nitrogen, its molecular weight being 4 against 28 for nitrogen. Helium will thus escape from the lungs much more quickly than nitrogen during decompression. Experiments on animals have so far shown that the safe decompression time for helium and nitrogen is somewhere about 1 to 3 or 4. To reduce the decompression periods to one third or one fourth would be a very great advantage.

Greatest Depths for Useful Work.—The greatest depth at which useful work has been accomplished by divers is 275 ft. This was at the salvage of the U.S.A. submarine "F4," sunk off Honolulu, by divers of the United States Navy using the British Admiralty decompression system described in the present article. The Spanish diver, Erostrus, recovered £9,000 worth of silver bars from a depth of 182 ft. Siebe, Gorman & Co.'s chief diver, the late Alexander Lambert, salvaged £70,000 worth of Spanish gold coin from the wreck of the "Alphonse XII" sunk in 165 ft. off Las Palmas. W. Ridyard brought up £50,000 worth of dollars from the "Hamilla Mitchell" lying in 150 ft. of water. These are a few examples of treasury recovery notable by reason of the great depths involved. But there have been many cases where far larger sums have been recovered from lesser depths, e.g., the case of the "Laurentic" in 130 ft., sunk during the World War, with gold on board to the value of five million pounds sterling, all but £40,000 worth of which was recovered by British naval divers. Then there is the case of the "Oceanic" from which specie, etc., to the value of £700,000 was salvaged by divers.

The sponge divers of the Mediterranean work at a maximum depth of about 150 ft., but they make exceedingly short stays on the bottom, and so, in most cases, avoid risk of pressure troubles. The pearl divers of Australia usually work at about 120 ft. Submarine operations on the great majority of harbour, dock and bridge works are conducted at depths of from 40 to 80 ft. The weighted tools employed by divers differ very little from those used by workmen on terra firma. Pneumatic tools, worked by compressed air conveyed from the surface through flexible tubes, are great aids, particularly in rock-blasting work.

Self-contained Diving Apparatus (fig. 10).—The first really practicable self-contained diving apparatus was designed by H. A. Fleuss working in conjunction with Siebe and Gorman, about 50 years ago. The original apparatus enabled a diver to do good work in the flooded Severn tunnel in 1882. The diver on that occasion had to travel nearly a quarter of a mile through the workings—encountering all sorts of obstacles, floating timber, etc., on his journey—to a heading in which he had to close an iron door and a sluice valve. Later, Fleuss and R. H. Davis improved the apparatus considerably. The apparatus supplies a

factitious, but perfectly respirable air by means of regenerating devices, thus making him independent of the surface. His dress, helmet and boots are of the ordinary patterns. Attached to a leather equipment carried on his back is (1) a cylinder of oxygen and air in certain proportions (it is dangerous to breathe pure oxygen at pressures above one atmosphere plus, hence the dilution), (2) a reducing valve connected to the cylinder, and passing the gas into the helmet through a tube connection at the requisite pressure and volume, (3) a watertight chamber, containing caustic soda, also connected by tube to the helmet. The diver's exhaled air is passed through the caustic soda, which takes up the carbonic acid, and, thus purified, comes back into the helmet where it mixes with the fresh oxygen and air which is constantly passing from the cylinder. This process of regeneration goes on automatically for from 45 minutes to two hours, according to the depth at which the diver may be working. The apparatus can be used at depths down to 150ft.

Recently, Neufeldt and Kuhnke have constructed a diving dress of steel and aluminum alloy, which, they claim, enables the wearer to do the work of a diver in the ordinary (flexible) dress. This diving suit is independent of outside air supply, and is designed to withstand the pressure due to the head of water at which the diver is working. The diver, therefore, breathes air at normal atmospheric pressure, thereby eliminating the effects due to excessive air pressure. Connection with the ship can be maintained by a cable and communication effected by a telephone. A diver equipped with the dress has recently (Aug. 1928) worked on the wreck of the Belgian steamer "Elizabethville," sunk in 1917 off Belle Isle, at a depth of 240 feet.

Diving Bells—The first designer of the diving bell may have received inspiration from the water spider which makes its home in a bell-shaped chamber of silk, anchored, orifice downwards, by silken threads to water weeds, etc. The hairs which cover the hinder part of the spider's body are long and hooked at the ends, and have the power of entangling air, so that, when it dives beneath the surface, the insect is partially enveloped in a bubble. The bell when first made is, of course, full of water. To expel the water, the spider disengages the bubble of air inside the bell, and so displaces a little water, the operation being repeated until the

originator of the diving bell, but actual records are not to be had. Of the records preserved to us, the most trustworthy is the description in the *Philosophical Transactions of the Royal Society*, 1717, of Dr Edmund Halley's bell, constructed of wood, and supplied with air by means of two closed barrels, with a hole in the bottom, and with a leather tube, connected at the top, the open end of the tube falling below the bottom of the barrel. The

FIG. 11.—SECTIONAL VIEW OF A DIVING BELL OF THE ORDINARY TYPE. Open at the bottom the water is kept out by compressed air pumped down from the surface. Illustration shows inlet valve, less telephonic apparatus, electric lamps, folding seats, behind which are slabs of cast iron serving as ballast to give the necessary sinking weight to the bell.

barrels were lowered and raised alternately. When the tubes were taken into the bell, the pressure of water, acting through the hole in the bottom of the barrel, forced the enclosed air into the bell.

Fig. 11 illustrates one of several Siebe Gorman ordinary diving bells, built of steel, as used during the construction of the National Harbour at Dover. Each measured 17ft long by 10½ft wide by 7ft high, and weighed 35 tons. It was lighted electrically, and fitted with telephonic apparatus which enabled the bell divers to converse with the engineers and crane and compressor attendants at the surface. Air was supplied to the bell by a steam-driven compressor housed on the gantry which carried the traveling cranes for lowering and raising the bell through the water to a maximum depth of 60ft, and also for lowering the concrete blocks. The air tube for the compressor was connected to a non return air inlet valve fitted in the crown of the bell. As in the case of the diving dress, an adequate supply of air at the right pressure is maintained to ensure proper ventilation of the bell, the excess escaping at the lower edge of the latter. The bell divers were employed in levelling the sea bed in readiness to receive the blocks, which weighed 40 tons apiece. Having levelled one section, the bell was moved to the next. The blocks were then lowered, and were placed in position by helmet divers. The bell divers, clad in woolen suits and watertight thigh boots, worked in two hour to three hour shifts. The cost of such a bell, with air compressor, telephone and electric lamps, is about £2,000.

The air lock diving bell comprises a steel working chamber similar to the ordinary diving bell already described, with the addition of a steel shaft attached to the roof. At the upper end of the shaft is an airtight door, and about 8ft below this is another similar door, the space between the two forming an air-lock. When the men wish to enter the bell, they pass through the first door and close it after them, and then open a valve and let into the lock compressed air from the working chamber till the pressure is equalized, they then open the second door and pass into the main shaft, closing the door after them. Access to the working

FIG. 10.—FEATURES OF THE SELF-CONTAINED DIVING DRESS AN APPARATUS WHICH NEEDS NO AIR SUPPLY FROM THE SURFACE.

- 1 Front view, showing emergency oxygen and air cylinder in weighted chamber.
- 2 Back view, showing oxygen and air cylinder, and exhaled air purifying chamber.
- 3 New German self-contained diving dress, invented by Neufeldt and Kuhnke. Made of steel cylinders. It permits diver to explore freely at depth of 40 fathoms (240 feet).

water is replaced entirely by air, the latter being re oxygenated by the same process. Pressure of water increases with its depth. Sink a diving bell to a depth of, say 33ft, and the air inside it will be compressed to about one-half its original volume, and the bell itself will be half filled with water. But keep up a supply of air at a pressure a little above that which is equal to the depth at which the bell is submerged, and you will not only keep the water down to the lower edge of the bell, you will also ventilate it and enable its occupants to work for hours at a stretch.

Tradition gives Roger Bacon, in 1250, the credit of being the

chamber is by ladder, secured to the side of the shaft. When returning to the surface, they reverse the operation, opening the lower door, entering the lock and closing the door again, then opening a valve to release the air pressure, when the upper door is opened and the men emerge to atmosphere. Some bells of this type are fitted with two shafts each with its air lock—one for the passage of the bell men the other for materials.

See R. H. Davis, *A Drugg Manual* (1920), *Report of British Admiralty Deep Diving Committee* (1927), *U.S.A. Bureau of Mines Report* on possibilities in the use of Helium Oxygen Mixtures as a Mitigation of Caisson disease (6th Annual Report, 1926). (R. H. D.)

DIVIDENDS Ordinary dividends are the current or accumulated net earnings appropriated for and distributed among stockholders of a corporation in proportion to their respective hold- ings and is determined by the class of their holdings.

In the United States, there are statutory rules that limit the payment of dividends by boards of directors of corporations. The most frequent general restriction is that dividends are payable only by solvent corporations only to the extent that the value of the assets exceeds the liabilities by an amount greater than the legal capital; that is, dividends are payable out of surplus. The major exceptions to this general restriction are made in connection with mining corporations operating with wasting assets. Within the statutory limits and the contractual rights in the case of preferred stock the authority of declaring and paying dividends is lodged with boards of directors.

Dividends are usually payable in cash on an annual basis, although on occasions distributions are made in the form of shares of stocks. The actual payment is made to stockholders of record. It should be noted that a stock dividend issued to a certain class of stockholders does not change the equity position of this class of stockholders.

Dividends on Preferred Stock—Many corporations obtain their capital by issuing both preferred stock and common stock. The preferred stockholders are entitled to a preferential dividend usually at a fixed rate, and the common stockholders get a portion of what remains after payment of the dividends on preferred stock. The dividend on preferred stock may be either cumulative or contingent on annually determined net earnings. When cumulative, if the net earnings for any year are insufficient to pay in full the fixed rate on preferred stock, the deficiency has to be made good out of net profits earned in subsequent years. The holders of noncumulative preferred stock have no right to dividends with respect to any year when the net earnings are insufficient. When the reported net earnings, however, are sufficient to provide for dividends to noncumulative preferred stockholders, the board of directors may still withhold payment of dividends in the interest of the corporation's financial position. In this instance, however, the rights of the holders of noncumulative preferred stock in the net earnings of the year involved are not eliminated.

Wasting Asset Dividends and Liquidating Dividends—Wasting-asset dividends and liquidating dividends should be distinguished from ordinary dividends. The board of directors of a corporation which is engaged in exploiting a natural resource need not determine the amount of depletion in ascertaining the net earnings of any year available for dividends. The amount distributed to stockholders of a mining corporation in the form of dividends may, therefore, be partly a return of capital. This leeway given to the boards of directors of mining companies is based on the idea that corporations with wasting assets otherwise would be converted into investment companies, not the purpose for which they were originally organized.

Liquidating dividends are, also, a distribution of capital. In the absence of creditors' claims and preferred stock, the board of directors of a corporation may distribute all or a portion of its capital to stockholders. In general, however, such a distribution among stockholders must be sanctioned by the holders of a large majority of the shares. Otherwise, the declaration and payment of liquidating dividends would eliminate the original purpose of the investment.

In the case of liquidating trusts, bankrupt companies and the like, liquidating dividends are paid to claimants and various classes of stockholders, in so far as the value of the liquidated assets permit.

Ex Dividend—When the price of a share of stock is quoted on the stock market as "ex dividend" it means that the price does not include the dividend which is just about to be paid on it. Stock market experience has shown that the question of dividend payment is no idly to become germane until the time approaches when the payment is drawing near. Under certain circumstances, there may be sufficient trading to influence the price of a share of stock in contemplation of a dividend declaration.

Assuming that no other change occurs in supply and demand conditions, the price of a share of stock between the payment of one dividend and that of the next should increase as the dividend payment date draws near. Then, when the quoted price is officially declared ex dividend, the market quotation will tend to fall by the net amount of the dividend. This does not necessarily happen although the tendency is for stock prices to rise as dividend dates approach. It has been suggested that potential buyers of shares of stock have a parity for those shares of common stocks upon which a payment of dividend can be expected in the near future. It has also been observed that potential sellers may object to parting from the opportunity of receiving a dividend and prefer to await market quotations which are ex dividend before effecting sales.

Stock exchange rules govern all cases of ex dividend marking and make provisions for various contingencies. The New York Stock exchange rules with respect to dates on which shares of stock shall sell ex dividend are as follows:

- (1) When transactions are not made for cash, shares of stock shall be quoted ex dividend on the full business day preceding the record date fixed by the board of directors of the corporation.
- (2) When transactions are made for cash, shares of stock shall be quoted ex dividend on the full business day following the record date.
- (3) The board of governors, in any specific case may, however, direct otherwise. (See STOCK EXCHANGE.)

Dividend Payments in the United States—Dividend payments are a substantial portion of the national income of the United States. Between 1926 and 1941, according to the estimates of the United States department of commerce, these distributions to stockholders did not fall in any one year below \$3,000,000,000. During the period 1928 to 1930, dividend payments were at an annual rate above \$5,000,000,000. When compared with a national income (in current dollars) ranging between \$55,000,000,000 to \$96,000,000,000 for the period 1926 to 1941, it is evident that the distributive share of the national income in the form of dividend payments is a significant amount. The table shows national income and dividend payments (both in current dollars) in the United States for the period 1927 to 1941, as estimated by the United States department of commerce.

National Income and Dividend Payments in the U.S., 1927-41

Year	National Income	Dividends
1927	\$76,200,000,000	\$5,000,000,000
1928	80,100,000,000	5,300,000,000
1929	83,100,000,000	5,000,000,000
1930	68,000,000,000	4,500,000,000
1931	34,100,000,000	4,300,000,000
1932	40,000,000,000	2,700,000,000
1933	47,300,000,000	2,700,000,000
1934	49,200,000,000	2,700,000,000
1935	55,200,000,000	2,900,000,000
1936	61,000,000,000	4,700,000,000
1937	71,300,000,000	4,700,000,000
1938	81,000,000,000	4,800,000,000
1939	70,000,000,000	3,600,000,000
1940	77,600,000,000	4,000,000,000
1941	92,000,000,000	4,400,000,000

BENJAMIN RAFFERTY—Gabriel A. D. Prentiss, *The Nature of Dividends* (1935), W. A. Paton, ed., *Accountants' Handbook*, pp. 1021-1055 (1943). (S. H. N.)

DIVIDIVI, the native and commercial name for the astrigent pods of *Caesalpinia coraria*, a leguminous shrub of the subfamily, Caesalpinioideae, growing in open, semi arid regions, especially above tidal flats of the coast from Mexico to northern South America and the West Indies. The plant is between 20 and 30 ft in height and bears white flowers. The pods are flattened and curl up in drying, they are about $\frac{1}{2}$ in broad, from 2 to 3 in long and of a rich brown colour. Dividivi was first brought to Europe from Caracas in 1768. The pods yield a high percentage of tannin of exceptional qualities.

DIVINATION, the process of obtaining knowledge of secret or future things by means of oracles, omens or astrology, from contact with superhuman or divine sources. Divination is practised in all grades of culture. The information is commonly held

to come directly or indirectly from superior, non human sources In the Bornean cult of the hawk the divine bird is regarded as knowing the future, or as a mere messenger Divination is largely employed to discover the cause of death, where it is assumed to be due to magic In some cases the spirit of the dead man is held to give the information, in others the living magician is the source of the knowledge

Divinatory methods may be classified as (a) internal, conditioned by change in the consciousness of the soothsayer, (b) external (a) Internal methods depend on (i) sensory or (ii) motor automatisms, or (iii) mental impressions, for their results (i) *Crystal gazing* is analogous to dreams, except that the vision is voluntarily initiated, though little, if at all, under the control of the seer (ii) *Shell hearing* and similar methods are less common In these the information is gained by hearing a voice (u) The divining rod (qv) is the best known example of this class In mediaeval and modern times water divining or *dowsing* (qv) has been largely and successfully used Similarly a sieve held suspended gives indications by turning, and divination by a suspended ring is found from Europe in the west to China and Japan in the east The ordeal by the Bible and key is equally popular, the book is suspended by a key tied in with its wards between the leaves and supported on two persons' fingers, and the whole turns round when the name of the guilty person is mentioned Divination by automatic writing is practised in China *Trance speaking* may be found in any stage of culture and in many cases the procedure of the magician or shaman induces a state of autohypnotism, at a higher stage these utterances are termed oracles (qv) and are believed to be the result of inspiration (iii) Observation shows that by the aid of mental impressions, akin to clairvoyance (qv), fortunes are told successfully by means of palmistry or by laying the cards, for the same "lie" of the cards may be diversely interpreted to meet different cases In other cases the impression is involuntary or less consciously sought, as in dreams (qv), which, however, are sometimes induced for purposes of divination by the process known as incubation or temple sleep Dreams are sometimes regarded as visits to or from gods or the souls of the dead, sometimes as signs to be interpreted symbolically (b) In external divination the process is by inference from external facts The methods are very various (i) The casting of lots, *sortilege*, was common in classical antiquity Similarly dice are thrown for purposes of sortilege, the *astragali* or knucklebones, used in children's games at the present day, were implements of divination In Polynesia the coco nut is spun like a teetotum to discover a thief In ancient times the poets were often consulted, more especially Virgil, whence the name *sortes virgilianae*, just as the Bible is used for drawing texts in our own day, especially in Germany (ii) In *haruspicy*, or the inspection of entrails, in *scapulomancy* or divination by the scapula or shoulder-blade, in divination by footprints in ashes, the diviner must take active steps to secure the conditions necessary to divination (See also HEPATOSCOPY) (iii) In the case of *augury* and *omens* (qv), the behaviour and cries of birds, and meeting with ominous animals, etc., may be voluntarily observed (iv) *Astrology* (qv) still finds believers among people of good education (v) In other cases the tie that binds the subject of divination with the omen giving object is sympathy The name of the life-index is given to a tree, animal or other object believed to be united by sympathetic ties to a human being so that the fate of the latter is reflected in the condition of the former (See the articles AUGURS, ORACLE, ASTROLOGY, OMEN, etc.)

DIVING see DIVERS AND DIVING APPARATUS

DIVINING-ROD The art of using a divining-rod for discovering something hidden is of immemorial antiquity, and the Roman *virgula divina*, used in taking auguries by means of casting bits of stick, is described by Cicero and Tacitus The particular form of *virgula furcata*, or forked twig of hazel or willow, described by G. Agricola (*De re metallica*, 1546), and in Schöner's Munster's *Cosmography* in the early part of the 16th century, used especially for discovering metallic lodes or water beneath the earth, must be distinguished from the general superstition The "dowsing" or divining rod dates from its use by prospectors for minerals in the German (Harz mountains) mining districts in the 15th century The *Schlagruthe* (striking rod) or forked twig of the German miners was brought to England by the merchant ventures of Queen Elizabeth's days for those engaged in the Cornish mines As mining declined in Cornwall its use was transferred to water finding

In modern times the professional dower (qv) is a "water finder," and there has been a good deal of investigation of his claims to be able to locate underground water, where it is not known to exist, by the use of a forked hazel twig which, twisting in his hands, leads him by its directing power to the place where a boring should be made A widespread faith exists, based on frequent success, in the dower's power Prof Sir W. F. Barrett was satisfied that the rod twists without any intention or voluntary deception on the part of the dower, and ascribed the phenomenon to "motor automatism" on the part of the dower, a reflex action excited by some stimulus upon his mind, which may be either a subconscious suggestion or an actual impression (obscure in its nature) from an external object or an external mind, both sorts of stimulus are possible, so that the dower himself may infer that the stimulus is an external object (like water) Like the "homing instinct" of certain birds and animals, the dower's power lies beneath the level of conscious perception, and the forked twig acts as an index of some material or other mental disturbance within him, which otherwise he could not interpret Not all dowers use a rod Some use a willow rod, or withy, others a hazel twig (the traditional material), others a beech or holly twig, or one from any other tree, others even a piece of wire or watch spring The best dowers have generally been more or less illiterate men, engaged in some humble vocation

DIVISION, a general term for the action of breaking up a whole into parts (from Lat. *dividere*, to break up into parts, separate) Thus, in political economy, the phrase "division of labour" implies the assignment to particular workmen of the various portions of a whole piece of work, in the musical terminology of the 17th and 18th centuries, the term was used for rapid passages consisting of a few slow notes amplified into a florid passage, i.e., into a larger number of quick ones The word is used also in concrete senses for the parts into which a thing is divided, e.g., a division of an army, an administrative or electoral division, similarly, a "division" is taken in a legislative body when votes are recorded for and against a proposed measure

Mathematics—In mathematics, division is the process of finding one of two factors when their product and the other factor are given The given product and factor are called the dividend and divisor respectively The factor required to be determined is called the quotient In the system of numbers consisting of the integers and fractions there is a uniquely determined quotient for every choice of dividend and divisor except when the latter is zero In dealing with integers, however, the division is possible only when the dividend is a multiple of the divisor If the dividend D is between dq and $d(q+1)$ —two consecutive multiples of the divisor d —then the integer q is called the quotient and the integer $D-dq$ the remainder, the process of finding the quotient and remainder is referred to as division with remainder Unique division with remainder is also definable in the division of polynomials in a single variable x by requiring the remainder to be of lower degree in x than the divisor The details of the division process are given in elementary arithmetic and in high school algebra textbooks (see ARITHMETIC and ALGEBRA)

A contraction of the usual division process when the dividend

is a polynomial in the variable x and the divisor is $x-r$ is known as synthetic division. Thus, if the dividend is ax^2+bx^2+cx+d the synthetic division by $x-r$ is arranged as follows

$$\begin{array}{r|rrrr} & a & b & c & d \\ & & ar & cr & fr \\ \hline & a & b+ar & c+cr & d+fr \end{array}$$

The numbers e, f, g are the sums of the two numbers directly above each. The remaining numbers are self-explanatory. The quotient and remainder are read from the bottom line, the quotient is $ax^2+bx+cx+d$ and the remainder is g . For instance, the quotient and remainder when $x^4-3x^3+x^2-7$ is divided by $x+1$ i.e. seen to be x^3-4x^2+5x-2 , respectively, from the following calculations

$$\begin{array}{r|rrrrr} & 1 & -3 & 1 & 0 & -7 \\ & & -1 & 4 & -5 & 5 \\ \hline & 1 & -4 & 5 & -5 & -2 \end{array}$$

(X)

Logic—In traditional logic, division is a technical term for the process by which a genus or wider class is differentiated into its subclasses or species. For example, the genus "Man" (mankind) has been divided by some anthropologists into three broad groups, Caucasian, Mongoloid and Negroid. These in turn have been divided into subclasses—the Caucasian into Nordic, Alpine, etc., the Mongoloid into Asiatic Mongoloid, American Indian, etc., the Negroid into Negro, Negrito and so on. Thus, logical division moves from the more general to the less general, breaking up wider concepts into narrower. It is closely related to the process of classification (qv) which moves, however, in the opposite direction, beginning with particulars and moving through an ascending series of classes to the widest possible genus. Division is also closely related, in Aristotelian logic, to definition (qv), the process of stating the nature of a species of thing by naming the genus into which it falls and then giving the differentia of this species that is, the characteristics by which it is distinguished from other species within the same genus. In any scientific or other intellectual work, these processes by which materials are organized are likely to go hand in hand. Especially are division and classification so intimately involved with one another that they are usually carried on at the same time in actual practice.

The rules of division, which apply also to classification, are

1. The division must be exhaustive. That is, every member of the genus must be included in one or another of the species into which the genus is divided. In the above example, if there were men who did not fit into any one of the three broad racial groups, the division would not satisfy the ideal conditions set forth in this rule.

2. The division must be exclusive, that is, each of the species must exclude the members of all other species, there must be no overlapping among these subclasses. This rule can be violated in several ways. One is to bring down to a certain level a class which belongs above it, or to bring up to a certain level a class which belongs below it. To group together as co-ordinate classes books, newspapers, magazines and printed matter would be illogical, for the last term includes the others. Nor would it be logical to place in a co-ordinate group newspapers, magazines and dailies, for the latter is a subdivision of one of the classes. An other violation of the second rule results from failure to observe the third rule, as will be explained.

3. The division must employ a single principle by which the species are differentiated from one another, and as far as possible must continue to employ this principle at all stages of the process. The traditional term for the basic principle is *fundamentum divisionis*. For example, the basic principle by which to divide the genus Man into various races might be skin colour. But other principles have been used, such as facial features, shape of head, cranial capacity, blood chemistry, type of hair, geographic distribution or some carefully selected group of traits. It would be a violation of the third rule to resort to one principle at first and then allow one or more different principles to intrude at the same level, as would be the case if races were divided into black-skinned, white-skinned, wavy haired and round headed peoples.

The use of more than one principle results in what is called cross division. From the example it is clear that the second rule, as well as the third, has been violated. To the three main rules a fourth is sometimes added.

4. Division must proceed gradually, that is, the genus must be resolved into the next (proximate) species. To leap over the intermediate levels, dropping down at once from the widest genus to the narrowest species, would have little value in organizing the materials under consideration.

From the examples given above, it can be seen that certain general problems are suggested by the process of division. Division may appear to be wholly arbitrary. If one *fundamentum divisionis* is selected, the subject matter is organized in one way, but a different principle gives a different grouping. On the basis of skin colour, mankind falls into certain races, on the basis of head shape, the racial groups are different. What are the "real" races? The difficulty of this problem, which has sometimes led anthropologists to debate the question whether there are distinguishable races at all, well illustrates the relation of logical division to more profound problems of scientific method and philosophy. It would seem to be clear that in some areas where division is applied, the choice of one principle rather than another is merely a matter of convenience. In the latter part of the 19th century and first half of the 20th a strong tendency developed among some groups of logicians and scientists to hold that this is all that is, or ever can be, the case. But the older philosophical and scientific ideal, that it is possible for man to find the real "joints" or dividing lines in nature itself, retained vigorous adherents through this same period. Some distinguished biologists affirmed that, however arbitrary other classifying terms in their science might be, the concept of species remained securely rooted in the objective realities of the animal kingdom. It is in general true, however, that the classical rules of division, which are from traditional Aristotelian logic, are too formal to be followed strictly by those who work in the sciences. It is frequently necessary, for example, to use one basic principle for one or more levels of the process of division, and then resort to a different principle in order to carry the division on down to lower levels. Thus, the second half of the third rule is often necessarily and justifiably rejected. The example of racial division given earlier in this article illustrates the difficulty of using a single principle.

A more radical result of the development of logical theory in the 19th and 20th centuries was the origin of theories in symbolic or mathematical logic which tended to displace the traditional Aristotelian logic altogether in most matters, including that of division. Notable in this connection is the theory of types, formulated by Alfred North Whitehead and B. A. W. Russell (*Principia Mathematica*, 2nd ed. [1925]). This approach placed the whole problem of classes in a new setting, and directed attention to the problems of "significant symbolism." But in spite of these later technical developments, and in spite of the many limitations of the formal rules of division, the classical conception of the process of division remains of great value in many areas where it is necessary for the human intellect to bring order into a field of scattered or chaotic materials.

(E. L. MN)

Military Science—In military science, division is the term given to a higher formation of an army. The infantry division, a permanent formation of all arms, is provided with every necessary means of subsisting, marching and fighting independently of any other formation. Divisions as we know them today were first formed by the French in 1770, but it was not till 100 years later that they became a permanent part of the army in peacetime. At the opening of World War I the French division, which may be taken as typical of European practice, comprised two infantry brigades each of two 3 battalion regiments, a cavalry squadron, two artillery groups each of three 6 gun batteries, engineer, medical and administrative units, in all, 12,000 men and 35 guns. The Prussian army introduced the divisional system at the opening of the Wars of Liberation in 1813, and it was adopted for the whole German army after the war of 1866, and continued in essentials unchanged down to 1914. Other European armies were slower to follow suit, but by the end of the 19th century practically all had

done so

In the British army the division had been the highest tactical and administrative unit throughout all the wars from the Peninsular to the Boer War, but it did not really become a part of the peacetime organization till the period of Lord Haldane's reforms in 1906. At the opening of World War I the British division differed in some important particulars from its continental counterparts, consisting as it did of three infantry brigades, each of four battalions, four artillery brigades, each of three 6 gun batteries, one 60 pounder battery, three field companies of engineers, three field ambulances, a signal company and administrative units such as the divisional ammunition column, a supply train and a veterinary section. Numerically, it was considerably stronger than the average continental division.

During World War I in all the armies the division became the tactical and administrative unit. Various modifications took place in its internal composition by 1918 the strength of the infantry had been greatly reduced, though the number of machine guns and automatic weapons had increased, divisional cavalry had disappeared, and the proportion of artillery and administrative units was larger. The majority of the remodelled armies of the postwar period showed similar tendencies in the composition of their higher formations. The division tended more and more to become the kernel of peacetime armies. The numerical reduction of the infantry went hand in hand with a rearmament which greatly increased its firepower and its potentialities for attack and defense, including defense against tanks. Divisional cavalry on the other hand was generally reintroduced while the lavish artillery allotment necessary for position warfare was reduced to an amount considered more suitable for mobile operations. Finally, the mechanization of transport considerably increased the radius of action of the whole formation.

In the British army, however, these tendencies were perhaps less marked than elsewhere. The 4 battalion infantry brigades were retained, the artillery, signal, engineer and medical units remained much as before the war and no divisional cavalry was allotted. The great increase in infantry firepower was, however, fully maintained, and the mechanization of transport proceeded further than in any other army, so that, though the framework of the British division changed but little in broad outline, it became a far more powerful engine of war than its prototype which took the field in Aug. 1914.

Cavalry divisions were first formed in war in the time of the first Napoleon, but though they became part of the French peacetime organization in 1875, the Germans, in common with the majority of European armies, had few or none in peace and formed them as required on the outbreak of war. They usually comprised six regiments, organized in two or three brigades, with horse artillery and ancillary units. Since World War I, in which, after the early stages, at any rate in the European theatres, cavalry was rarely able to carry out its normal functions, the general tendency has been to remodel them as light divisions, of which cavalry forms only a proportion of the combatant strength, mechanized units, such as armoured cars, motor machine guns, cyclists, artillery and mechanical transport, have been added to increase mobility and firepower. (See ARMY.)

United States Army.—The division is the highest tactical and administrative command in the United States army in time of peace. Prior to World War I the regiment was the highest. Provisional manoeuvre divisions were assembled in Mexico in 1911 and again in 1913, largely under the influence of conditions on the Mexican border. Theirs, however, was only a transitory existence. The 1928 divisional organization of the army of the United States was a World War I development.

The 1928, or square, divisional organization was lacking in fire power and flexibility. To remedy these defects, a new, triangular organization was evolved. This modern structure had its initial testing in the United States in extensive manoeuvres prior to World War II. In actual combat from 1941 to 1945, the new triangular division proved far superior to the former square type, providing increased firepower and being capable of rapid adaptation to the demands of a constantly shifting type of warfare which

frequently involved combinations of land, sea and air power.

Initial strength of the triangular division was set at 624 officers, 6 warrant officers and 14,615 enlisted men. Organizations provided are: division headquarters, headquarters and military police company, signal company, reconnaissance troop, engineer battalion, medical battalion (with attached medical troops), quarter master battalion, chaplains, 3 infantry rifle regiments, division artillery.

Each infantry rifle regiment has a strength of 110 officers, 1 warrant officer and 3,229 enlisted men. The interior organization of the regiment includes a headquarters and band, 1 service company, a headquarters company, an antitank company, and 12 light infantry companies, A to M, inclusive, grouped into 3 battalions each of which has a strength of 28 officers and 604 men.

Division artillery (truck drawn) includes a total of 121 officers, 1 warrant officer and 2,533 enlisted men. Interior organization includes headquarters and band, headquarters battery, three 105 mm. howitzer battalions (26 officers and 958 enlisted men to each battalion) and one 155 mm. howitzer battalion.

Armament of the division includes

Pistols, automatic, cal 45	7,167
Rifles, U.S., cal 30 M1	6,942
Rifles, automatic, cal 30, Browning M1918 A 2	375
Guns, submachine, cal 45	14
Guns, machine, light, cal 30, M1919 A 4	14
Guns, machine, Browning, cal 30, M1917 (H)	17
Guns, machine, Browning, cal 50, M2, flat	36
Guns, machine, Browning, cal 50, M2 (HB)	27
Guns, 37 mm AT	60
Mortars, 60 mm	84
Mortars, 81-mm	96
Guns, 75 mm	8
Howitzers 105-mm	16
Howitzers, 155-mm	12

Division vehicles

Ambulances, 1 ton, cross country	40
Cars, light 5 passenger sedan	70
Cars, scout	16
Motorcycles, solo	25
Motorcycles, with sidecars	14
Tricycle, motor	7
Trucks	1,326
Special vehicles	7
Trailers	267

DIVORCE. Marriage, as distinguished from concubinage or promiscuous sexual intercourse, is a relationship which envisages in its inception a lifelong union of the parties. Many legal codes, however, provide for the dissolution of this union, for various reasons, during the lifetime of the parties. Such dissolution is known as divorce.

Lower Culture Groups.—Among a few uncivilized peoples marriage is said to be indissoluble or divorce unknown, and among many others, divorce is said to be rare or marriage as a rule to last for life, but there are also many tribes in which divorce is reported to be of frequent occurrence or marriage of very short duration. Because of the defective character of the information it is impossible to say anything definite about the comparative prevalence of lifelong unions and of divorce among the lower races in general, or about the duration of marriage at the different grades of economic culture compared with one another. It is interesting, however, to note the universal or almost universal prevalence of lifelong unions among some of the lower hunters and incipient agriculturists, such as the Veddas of Ceylon, the Andamanese, the Orang Melayu and Orang Akit of Sumatra, and the "pure" tribes of the Malay peninsula. Somewhat more definite than the information we possess of the actual prevalence of divorce among the simpler peoples are the statements as to the circumstances in which their customs allow it to be practised. Among a large number of tribes the husband is said to be able to dissolve the marriage at will or on the slightest grounds or pretexts, and in the majority of these cases a similar right is granted to the wife. But we are also frequently told that a man must not divorce his wife and a wife not separate from her husband without just or good cause. The most generally recognized ground for divorce is probably adultery on the part of the wife, and among some peoples the wife is said to have a right to divorce an

unfaithful husband. A very frequent cause of divorce is barrenness in the wife while the birth of a child may make marriage indissoluble, and sometimes we are told that the wife can effect divorce if the husband proves impotent. Other recognized grounds for divorce are as follows: a man may divorce his wife if she is lazy or negligent, if she suffers from a foul or incurable disease, if she becomes too old, if ill her children die or, of course, if she deserts him. The wife again may dissolve the marriage if the husband neglects or ill treats her, if he deserts her or if she has a strong repugnance to him. Among some natives of eastern central Africa the wife may divorce a husband who fails to sew her clothes. Among the Shins of Buruti, should the husband take to drinking or otherwise misbehave, the wife has the right to turn him adrift and to retain all the goods and money of the partnership.

Semitic Peoples.—Among Semitic peoples the husband has had or still has the legal right of repudiating his wife at will. In Babylon, according to the laws of Hammurabi, however, the wife and even a concubine had certain pecuniary guarantees against arbitrary divorce, and she might also herself in certain circumstances claim a divorce, or at least separation. The right of the husband to repudiate his wife if his pleasure is the central thought in the system of Jewish divorce law, and the rabbis neither did nor could set it aside, although they gradually tempered its severity by numerous restrictive measures. It ceased to exist in practice and was at last, in the earlier part of the 19th century, formally abolished, whereas the husband retained the right to divorce his wife if a good cause could be shown. On the other hand, the wife has no right to divorce her husband. But the Mishnah allowed her to sue for divorce, and if the court decided that she was entitled to be divorced the husband was forced to give her a bill of divorce although he was supposed to give it of his own free will and accord. In the modern state of Israel there is no distinction between nullity and divorce, the grounds for divorce being bigamy, breach of the law of affinity, the wife's adultery or refusal of marital rights, the husband's leprosy, vice, neglect, refusal to maintain the wife, impotence or other bodily defects, and behaviour disturbing to the common life. Divorce may also be obtained by mutual consent.

As the ancient Hebrews, so the pagan Arabs let the husband repudiate his wife whenever he pleased, and subsequently this unlimited customary right was crystallized in Mohammed's law, and it Mohammedan, as in Jewish law, the wife can never divorce her husband, although she may take steps leading to the dissolution of her marriage. When she desires a divorce she may obtain from him a release from the marriage contract by giving up either her settled dower or some other property, and when the husband is guilty of conduct that makes the matrimonial life intolerable to the wife or when he fails to fulfil his engagements she has the right of preferring a complaint before the judge and demanding a divorce by authority of justice. But the facility with which Mohammedan women can effect a dissolution of their marriage is influenced by local custom. So also the frequency of divorce differs considerably in different parts of the Mohammedan world. In some parts it is practised to an extent that is almost without a parallel, whereas among the Mohammedans of India the husband seldom exercises his right to divorce his wife without any special reason. This may be due to Hindu influence.

Hindu Practice.—With orthodox Hindus marriage is a religious sacrament which cannot be revoked. A woman convicted of adultery may be deprived of her status and turned out of her caste but even in this case divorce in the ordinary sense is an impossibility. The law, however, was not always equally stringent. At present the orthodox Hindu law of divorce is more or less disregarded by certain low castes in the north of India and by many castes, both high and low, in the south, among whom usage has superseded texts, agreeably to such usage the granting of a divorce, or the recognition of a divorce as one properly made, is the duty of the caste.

Early Greeks and Romans.—Among the Greeks and Romans in the early days, as among the Hindus, marriage evidently was a union of great stability, although in later times contrary to what was the case among the Aryans of India, divorce became easy and

frequent. Among the Greeks of the Homeric age divorce seems to have been almost unknown, but afterward it became an every day event in Greece. According to Attic law the husband could repudiate his wife whenever he liked and without stating any motives, while the wife could demand a divorce by appealing to the archon and stating the motives for her demand. A Roman marriage was perhaps at no time indissoluble, but the specifically patrician kind of marriage, by *conferreatio*, was at any rate very nerily so. The other forms of marriage, not being of the same mystical and sacramental character, could be dissolved without difficulty. The husband's legal authority in regard to the dissolution of a marriage with *manus* (i.e., the legal or customary provision whereby the wife passed into the almost unrestricted power of her husband) was absolute, whereas in the old law a wife *in manus* was as little a free party to the act of divorce as a slave was a free party to that of emancipation. Yet in practice the husband's right was no doubt more or less checked by public opinion and, as it seems even by the censors, it was said that for 500 years no one took advantage of the liberty of divorce. In regard to a "free" marriage, which implied that the wife did not fall under the *manus* of her husband, the rule of divorce was very different. The dissolution of such a marriage could be brought about either by mutual agreement between both parties or by the will of one party only. The rules of divorce that were recognized in the case of a free marriage were afterward practically extended to marriages with *manus*, and in the end marriages with *manus* fell into disuse altogether. Toward the close of the republican era and during the empire divorce was very frequent among the upper classes, almost all the well-known ladies of the Ciceronian age were divorced at least once.

Teutonic Peoples.—According to the old customary law of the Teutonic peoples a marriage could be dissolved by agreement between the husband and the woman's kin, and the husband was entitled to repudiate his wife if she was sterile or guilty of conjugal infidelity and perhaps for some other offences. On the other hand the wife had originally no right to dissolve the marriage. (E. W. K.)

Divorce Law.—Divorce is the dissolution, in whole or in part, of the tie of marriage. In the main the practice in the legal systems of the civilized world is derived from the Roman law and the canons of the Christian churches. In countries in which the Roman Catholic creed is supreme, subject to certain exceptions indicated later, complete divorce is *vinculo matrimonii* (the bond of marriage) is not legally possible, though the same result may be achieved in rare cases by the ecclesiastical courts declaring that the marriage was a nullity. The papal decree of divorce *a mensa et thoro* (from bed and board), which is the practice in the Republic of Ireland and other Roman Catholic countries and is represented in English laws by judicial separation, leaves the parties still married, neither being able to remarry during the lifetime of the other. In the end it was due to the spread of Christianity and the authority of the Church of Rome that marriage came to be regarded not only as a civil contract but also as a sacred bond.

How far the Founder of the Christian religion laid down any moral law in regard to divorce has always been a matter of controversy, because of the form of His declaration that has come down to us and the different conceptions then existing of the conjugal relations. monogamy, so far as a husband was concerned, had not in His time been established. The rule of the Mosaic law was expressed as follows: "When a man hath taken a wife and married her, and it come to pass that she find no favour in his eyes, because he hath found some uncleanness in her, then let him write her a bill of divorcement, and give it in her hand, and send her out of his house. And when she is departed out of his house, she may go and be another man's wife" (Deut. xxiv, 1, 2).

The Pharisees asked Jesus "Is it lawful for a man to put away his wife for every cause?" Jesus replied "What God hath joined together let no man put asunder" and also said "Moses, because of the hardness of your hearts, suffered you to put away your wives, but from the beginning it was not so." Then came the declaration which is the main basis of the canon law: "Whosoever shall put away his wife, except it be for fornication, and shall marry

another, committeth adultery, and whose marneth her which is put away doth commit adultery" (Matt xix, 3-9). Practically the same formula was used in the Sermon on the Mount (Matt v, 32) and in Luke xvi, 18 and Mark x, 11-12 with the important omission of the exception for fornication, and many modern textual critics have regarded this exception as the interpolation of a scribe.

The Roman Church has always interpreted the exception of fornication as applying only to incontinence by the wife before marriage discovered by the husband after marriage, and has treated it, not as just cause for dissolution of marriage, but as invalidating the marriage itself. It will be observed also that right down to the 20th century incontinence has been regarded as a matrimonial offense only if committed by the wife. In most countries where the civil law allows complete divorce husband and wife are now on an equal footing as to the grounds of divorce.

The Roman Law of Divorce.—The history of divorce took its earliest colour from that conception of the *patria potestas*, or the power of the head of the family over its members, which enters so deeply into the jurisprudence of ancient Rome. The wife was transferred at marriage to the authority of her husband, *in manus*, and consequently became so far subject to him that he could, at his will, renounce his rule over her and terminate his companionship, subject at once to an adjustment of the pecuniary rights which were disturbed by such action. As early, however, as the time of Romulus, it is said that the state asserted its interest in the permanence of marriage by forbidding the repudiation of wives unless they were guilty of adultery or of drinking wine, on pain of forfeiture of the whole of an offender's property, one-half of which went to the wife, the other to Ceres. But the law of the Twelve Tables allowed freedom of divorce. At last the *lex Julia de adulteris*, while recognizing a power of divorce both in the husband and in the wife, imposed on it, in the public interest, serious restrictions and consequences. It required a written bill of divorce (*libellus repudi*) to be given in the presence of seven witnesses, who must be Roman citizens of age, and the divorce had to be publicly registered. In this way a wife could divorce a lunatic husband, or the *paterfamilias* of a lunatic wife could divorce her from her husband. The *lex Julia* was followed by a series of acts of legislation extending and modifying its provisions.

In A.D. 449 divorce was made easier by Theodosius and Valentinian.

The modification in the civil law of Rome effected by Justinian under the joint influence of the previous law of Rome and that of Christianity was remarkable. Divorce by mutual consent, hitherto, as we have seen, absolutely free, was prohibited except in three cases: (1) when the husband was impotent, (2) when either husband or wife desired to enter a monastery, and (3) when either of them was in captivity for a certain length of time. At a later period Justinian, under the influence of the Christian idea of marriage, placed a further restriction or even prohibition on divorce by consent by enacting that spouses dissolving a marriage by mutual consent should forfeit all their property and be confined for life in a monastery (which was to receive one-third of the forfeited property, the remaining two-thirds going to the children of the marriage). The prohibitions of Justinian on divorce by consent were repealed by Justin II, his successor.

Justinian further re-enacted, with some modifications, the power of divorce by a husband or wife against the will of the other. Divorce by a wife was allowed in five cases: (1) the husband's being party or privy to conspiracy against the state, (2) attempting his wife's life, or failing to disclose to her plots against it, (3) attempting to induce his wife to commit adultery, (4) accusing his wife falsely of adultery, (5) taking a woman to live in the house with his wife, or, after warning, frequenting a house in the same town with any woman other than his wife. A husband was allowed to divorce his wife for any one of seven reasons: (1) failure to disclose to her husband plots against the state, (2) adultery, (3) attempting or failing to disclose plots against her husband's life, (4) frequenting dinners or balls with other men against her husband's wishes, (5) remaining from home against

the wishes of her husband except with her parents, (6) going to the circus, theatre or amphitheatre without the knowledge or despite the prohibition of her husband, (7) procuring abortion.

The Canon Law.—The canon law of Rome was based on two main principles: (1) that there could be no divorce *a vinculo matrimonii*, but only a *mensa et thoro*, i.e., separation, (2) that no divorce could be had at the will of the parties, but only by the sentence of an ecclesiastical court. It is thus apparent that there was no divorce in the sense in which it was defined at the beginning of the article. But the canon law held the marriage to be null and void if (*inter alia*) the parties were within certain prohibited degrees of consanguinity or affinity, and by the middle ages the degrees of consanguinity and affinity which invalidated a marriage were so much extended as to make unilament of marriage possible on the flimsiest of grounds. For example, in the reign of Edward III a marriage was annulled because the husband, before his marriage, had stood godfather to a female cousin of his future wife (Year Book 29 Edward III, f. 31).

GREAT BRITAIN

In England the law of divorce, being based on the canon law of Rome, was practically unchanged until the Matrimonial Causes Act, 1857. Divorce *a mensa et thoro* could only be granted by the ecclesiastical courts, which were invested with this jurisdiction, apart from a break during the Commonwealth, until 1857. These were the courts of the various dioceses, including that of the archbishop of Canterbury, the court of arches, and that of the rich bishop of York, the consistory court of York. An appeal lay to special delegates appointed by the crown *ad hoc*, until in 1832 the judicial committee of the privy council was given this appellate jurisdiction. Adultery and cruelty were the main grounds for this sort of divorce allowed by the ecclesiastical courts, and the principles acted upon by those courts are still those imposed by statute upon the present courts in regard to judicial separation, except that desertion was added by the 1857 act as a ground for a decree. As regards adultery a mere confession by a spouse of her guilt was not regarded by the canon law as a sufficient ground for a decree, if uncorroborated, and in the present practice in cases for dissolution of marriage a confession has to be supported by some sort of circumstantial evidence in the English court. In general the principle was accepted, and is still the rule, that if an illicit affection is proved and there are opportunities by association to gratify a guilty passion, then a *prima facie* case is made out, justifying a decree if there is no defense.

As regards cruelty the definition accepted by the ecclesiastical courts as that of the canon law is the same now. It was accepted by the house of lords in *Russell v Russell* (1897 A.C. 305), in which "legal cruelty" was defined as conduct of such a character as to have caused danger to life, limb or health (bodily or mental), or as to give rise to a reasonable apprehension of such danger. Those who wish to read the classic exposition on the subject of legal cruelty should read the judgment of Lord Stowell in the case of *Evans v Evans* (1790, 1 Hag. Con., 35). Thereafter there were innumerable decisions all showing that the court is not bound by any cast iron rule in its interpretation of what constitutes cruelty within the range of this definition.

Apart from a bare denial the canon law allowed three grounds of answer: (1) *compensatio criminis* was the committal by the spouse bringing the charge of the same matrimonial offense in which case the petitioner could be refused relief, (2) *condonatio* was complete forgiveness of the offending spouse by the other with full knowledge of the facts. Resumption by a husband of marital relations with his wife when he has full knowledge of her adultery is conclusive proof of condonation under the English divorce law, but resumption by a wife of marital relations with a guilty husband, with full knowledge, is not necessarily conclusive proof of condonation on her part. A matrimonial offense even of a different kind revives the former one, even if condoned. Condonation was a bar to relief, and still is, (3) *Connivance*. This is also a bar to relief, and always was, as it was held that a man could not avail himself of a charge if he did not appear with clean hands. The presumption of law is against connivance, and

the intention must be clearly shown for the court to refuse the petitioner relief. The petitioner need not be the active agent in the adultery of the other spouse. He may be guilty of connivance merely by neglect or indifference, though in that case the modern plea under the English statute law would probably come under the head of *conduct conducive*, which is in some cases hardly distinguishable from connivance and may equally be held a bar to relief.

Collusion between the parties for the purpose of presenting a false case to the court was also held by the ecclesiastical courts to be a bar to relief whether it was an agreement to give the appearance of having committed adultery when none had occurred or merely to withhold material facts from the knowledge of the court. The principle in the words of Lord Stowell is that there is no real injury "where there is a common agreement between the parties to effect their object by trial in a court of justice." It applies to any agreement not to defend, even where the agreement is disclosed to the court. In the law of divorce in England collusion may be held to exist not only when a false case is presented but also where there is a good case. Thus in a suit where the husband made provision for the future of his wife pending divorce proceedings Lord Merivale presiding though granting a decree, uttered a warning against any transaction pending divorce proceedings which raised a suspicion of collusion. In another case a divorce petition was dismissed in the first place because of an agreement by which the petitioner received a certain sum in advance in respect of damages from the respondent, and his second petition on a later charge was dismissed because by taking such sum he had connived at the further adultery of his wife. A party may show, however, that the negotiations with a view to a collusive bargain were abortive, or that the collusive agreement had been wholly spent in operation.

The ecclesiastical courts provided for the pecuniary rights of the wife by granting to her alimony during the progress of a suit, and a proper allowance after its termination in cases in which she was successful. Such payments were dependent on the pecuniary means or *faculties*, as they were termed, of the husband and were subject to subsequent increase or diminution in proper cases. But the ecclesiastical courts did not deal with the custody of the children of the marriage, it being probably considered that that matter could be determined by the common law rights of the father or by the intervention of the court of chancery.

As regards suits for divorce any substantial delay might lead to the imputation of acquiescence or even condonation. To that extent, at least the maxim *vigilantibus non dormientibus jura subveniunt* applied. Desertion by either party to a marriage, except as giving rise to a suit for restitution, was not treated as an offense by canon law in England. It formed no ground for a suit for divorce and constituted no answer to such a suit by way of recrimination. It might indeed deprive a husband of his remedy if it amounted to connivance, or perhaps even if it amounted only to culpable neglect.

Conjugal rights are those rights which a husband and wife have to each other's society, though the exact scope of this consortium has not been defined. When either party continues to refuse to render these rights to the other, they may be enforced by a suit for the restitution of conjugal rights. Until the grounds of complete divorce were equalized in 1923, the procedure of restitution was mainly used by wives to shorten the statutory period of desertion, noncompliance by the husband with a decree being followed by the wife's petition for divorce on the dual grounds of adultery and desertion.

Simulation of marriage is a persistent claim by a person of a marriage falsely alleged to have taken place between himself or herself and the complainant, who petitions for a decree enjoining perpetual silence on the person alleging such marriage in regard to it. In these days such a remedy is rarely required, though it was not an uncommon proceeding when "Fleets" and other irregular marriages were frequent and rights to property were involved. The procedure might still be useful for obtaining a declaration as to the validity of a disputed marriage in cases where the procedure under the Legitimacy Declaration act, 1858, re enacted in

the Matrimonial Causes act, 1950, section 17, is not convenient or applicable. The most historic case in which jactitation arose was the duchess of Kingston's case in 1776, reported in the State Trials. The only case to be reported for a quarter of a century was in 1930, when the petition was granted.

Criminal Conversation—Up to the Matrimonial Causes act, 1857, a husband could bring an action for damages against his wife's paramour (action for criminal conversation). It was a common law suit, and the damages were estimated according to the loss he was supposed to have suffered by the seduction and loss of his wife. This procedure was abolished by the 1857 act and grafted upon the new procedure in divorce by way of a separate prayer for damages against the corespondent in a petition for dissolution. In theory the damages are assessed on the same principle, though in practice a jury often fixes the amount at a figure calculated to inflict a severe punishment on the corespondent. If a petitioner for divorce or the respondent husband dies before the petition comes to trial, the petition is "abated," i.e., abandoned, the matrimonial tie having been dissolved by death. But if it is the respondent wife who dies the husband's prayer for damages against the corespondent may be pursued to trial.

It was for some time supposed after the Reformation that the sentences of divorce pronounced by the ecclesiastical courts acquired the effect of allowing remarriage, and such divorces were in some cases granted. In the marriage of Northampton's case in the reign of Edward VI the delegates, as one of the steps in a series of political manoeuvres, pronounced in favour of a second marriage after a divorce *a mensa et thoro*. They did not purport to dissolve the first marriage, and when Northampton was later convicted of treason his first marriage was restored by act of parliament. It was, however, finally decided in Foljambe's case, in the 44th year of Elizabeth, that a marriage validly contracted could not be dissolved for any cause. In 1670 a private act of parliament was granted in the case of Lord de Roos and this was followed by another in the case of the duke of Norfolk, submitted in the sessions 1692, 1699 and 1700, meanwhile (1697-98) the earl of Maclesfield had obtained a parliamentary divorce. Such acts were, however, rare until the accession of the house of Hanover, only five acts passing before that period. The jurisdiction thus assumed by parliament to grant absolute divorces was exercised with great care. They were very expensive and, in all, only 229 were successfully promoted.

The Acts of 1857, 1860 and 1866—The Matrimonial Causes act (which came into operation on Jan. 1, 1858) embodied two main principles: (1) the constitution of a lay court for the administration of all matters connected with divorce, (2) the transfer to that court, with as little change as possible, of the powers exercised in matrimonial matters by (a) the house of lords, (b) the ecclesiastical courts, (c) the courts of common law.

The functions of the new court, termed "the court for divorce and matrimonial causes" (after 1875, the divorce court, part of the probate, divorce and admiralty division of the high court) were practically entrusted to the judge of the court of probate (which was also established in 1857), termed the "judge ordinary" who thus in matters of probate and divorce became the representative of the former ecclesiastical jurisdiction. The parties to a suit obtained the right of trial by jury of all disputed questions of fact, and the rules of evidence of the common law courts were made to apply. An appeal to the full court was given in all matters, which the judge ordinary was enabled to hear sitting alone.

So this court were transferred all the powers of the ecclesiastical courts with regard to suits for divorce *a mensa et thoro*, to which the name was given of suits for "judicial separation," nullity, restitution of conjugal rights and jactitation of marriage. In all such proceedings it was expressly enacted (section 22 [comprised in sections 32 and 103 of the Judicature (Consolidation) act, 1925]) that the court should act on principles and rules as nearly as possible conformable to the principles and rules of the ecclesiastical courts. Judicial separation could be obtained by either husband or wife on adultery or cruelty or desertion continued for two or more years.

There were also transferred to the court powers equivalent to those exercised by the legislature in granting absolute divorce. The husband could obtain a divorce for adultery, the wife could obtain a divorce for adultery coupled with cruelty or desertion for two or more years, and also for incestuous or bigamous adultery or rape or unnatural offenses. As has been explained above, connivance, condonation or collusion continued to be absolute bars to divorce, and the court was given discretion to refuse relief where the petitioner had been guilty of adultery or conduct conducing to the respondent's adultery or had delayed unreasonably in prosecuting his suit.

This act assigned a new force to desertion. The ecclesiastical law regarded it only as suggestive of connivance or culpable neglect. But the act of 1857 made it (1) a ground of judicial separation if continued for two years, (2) a ground in part of dissolution of marriage if continued for the same period, (3) a bar, in the discretion of the court, to a petition for dissolution, though it was not made a bar to a suit for judicial separation.

Section 32 provided, in case of dissolution, for maintenance of the wife by the husband on principles similar to those recognized by the ecclesiastical courts, and section 45 for the settlement of the property of a guilty wife on her husband or children. By later acts of 1859 and 1878 provision was made for altering settlements made in contemplation or in consequence of a marriage. The act (section 35) provides also, in all divorce proceedings and in those of nullity, for provision for the custody, maintenance and education of children by the court. It was made obligatory to join an alleged adulterer in the suit, and damages (section 33) might be claimed against him, and he might be ordered to pay the cost of the proceedings (section 34).

The act of 1857 also provided (section 21) that a wife deserted by her husband might apply to a magistrate in petty sessions and obtain an order which had the effect of protecting her earnings and property, and during the currency of such order of protection a wife was to be in the same position as if she had obtained an order for judicial separation. The effect of this section appears to have been small, but the Summary Jurisdiction (Married Women) act, 1895, now reinforced by the Maintenance Orders act, 1950, afforded a cheap and speedy remedy to all classes. The act of 1857 made no provision as to the name to be borne by the wife after a divorce, and this omission led to litigation in the case of a peer's wife, in *Cowley v. Cowley* (1901, A.C. 450), in which Lady Cowley was allowed to retain her title.

By the act of 1860 a very important change was made, hiving for its object a practical mode of preventing divorces in cases of connivance and collusion or of misconduct of the petitioner. It was provided that a claim of dissolution (a provision afterward extended to decrees of nullity) should in the first instance be a decree *nisi* which should not be made absolute until the expiration of a period then fixed at not less than three months, but by subsequent legislation enlarged to not less than six. Under a general court order, as authorized by statute, the period was later cut down to six weeks. During the interval which elapsed between the decree *nisi* and such decree being made absolute, power was given to any person to intervene in the suit and show cause why the decree should not be made absolute, by reason of its having been obtained by collusion, or by reason of material facts not having been brought before the court. At any time before the decree was made absolute, the queen's proctor, if led to suspect that the parties were acting in collusion for the purpose of obtaining a divorce contrary to the justice of the case, might under the direction of the attorney general intervene and allege such case of collusion. It was established in *Sloggett v. Sloggett* (1928, P. 148, 44 The Times L.R., 394) that it was open to the king's proctor by direction of the court to intervene during the progress of a divorce suit before decree *nisi* and to call new evidence, not only when collusion is in question but in regard to other matters.

By an act of 1866 the court was given power to order a guilty husband to make provision for the maintenance of his former wife on the marriage being dissolved, and by an act of 1907 the court was enabled in suitable cases to order the husband to make similar provision when he was the petitioner and she the guilty

spouse. Additional powers to make orders for maintenance were given to the high court by the Matrimonial Causes act, 1950. From time to time the law of evidence in the divorce court was varied by statute until in 1866 it was enacted that no witness in any proceeding should be asked or be bound to answer any question tending to show that he or she had been guilty of adultery, unless in the same proceeding that witness had given evidence in disproof of the alleged adultery. This was still the law at mid 20th century.

The 1912 Commission Report.—The royal commission on divorce and matrimonial causes, after sitting for three years, completed its monumental labours in Nov. 1912 and by a majority report recommended important changes in the substantive law of divorce. The more important recommendations of the majority report were as follows: (1) hearing of divorce locally by commissioners of the high court, (2) powers of magistrates to make orders having the permanent effect of a decree of judicial separation to be abolished and replaced by a simple process in the high court, and husbands to be entitled to separate orders on the grounds of cruelty, habitual drunkenness and wilful desertion, equally with wives, (3) amendment of law so as to place the two sexes on an equal footing as regards the grounds of divorce, (4) five new grounds for divorce to be desertion for three years, cruelty, incurable insanity after five years' confinement, habitual drunkenness found incurable after three years from first order of separation and imprisonment under commuted death sentence, (5) habitual drunkenness as a ground for judicial separation, (6) provision for overcoming difficulties of jurisdiction as to domicile and residence, (7) unsoundness of mind, actual or incipient, at the time of the marriage, if unknown to the petitioner, and the fact that a spouse was suffering from a venereal disease unknown to the other, or the wife pregnant by another man, both at the time of the marriage, to be grounds for nullity, (8) provision for proceedings *in forma pauperis*, (9) no reports of divorce suits until a case is finished, and divorce judges to forbid or limit reports at their discretion.

In their minority report the archbishop of York (Cosmo Gordon Lang), Sir William Anson and Sir Lewis Diddin confined their recommendations to placing the sexes on the same basis as to grounds of divorce and to accepting the above recommendations as to the ground for nullity, plus that of wilful refusal to consummate the marriage.

By the Matrimonial Causes act, 1923 (sometimes called the Ent-whistle act from the name of its chief sponsor), it was provided that since July 18, 1923, any act of adultery by a husband would entitle his wife to a divorce. This act was repealed but re-embodied in the Judicature (Consolidation) act, 1925. Thus the royal commission's proposal in (3) above was carried into effect, and an immense change made in the law of divorce, in keeping with the spirit of the Sex Disqualification (Removal) act, 1919, but in contradistinction to the principle which actuated the divorce statutes of the 19th century. Thus a woman might now divorce her husband for a single act of infidelity. As a consequence of the alteration in the law the number of wives' petitions increased in a marked degree. Moreover the procedure of restitution of conjugal rights, mostly utilized up to 1923 for the purpose of shortening the statutory period of two years for desertion, became extremely rare.

By the Administration of Justice act, 1920, provision was made for the local hearing of undefended divorce suits on assize. Under the Legal Aid and Advice act, 1949, replacing and vastly extending the previous rules relating to poor persons, special provisions were made for persons desirous of petitioning for divorce. Solicitors and counsel acting for assisted persons are paid out of a special legal aid fund to which persons aided may be asked according to their income and assets, to contribute. This brought divorce within the range of people whose small means formerly discouraged this resort to the court.

By the majority of three law lords to two the house of lords in *Russell v. Russell* (1924, A.C. 687) effected a retrograde movement in the law of evidence by denying to spouses the right of stating on oath anything as to the possibility of marital access, if such evidence would tend to bastardize a child. The judge of first

instinct and three lords justices of appeal had admitted the evidence in question and the majority decision reversed the accustomed practice of the divorce court. The decision involved undue hardship especially on poor litigants though subsequent judgments reduced its effect to the lowest possible range. The law was altered by statute in 1949 when it was provided that the evidence of a spouse should be admissible.

Notably after World War I the attitude of the court changed in several important respects in the direction of greater humanity. Lord Macnaghten in his judgment in *Blunt v Blunt* (1905, P. 20) showed that in exercising his discretion in favour of a spouse who had himself been guilty of adultery, such action was not inconsistent with the interests of morality at large. In exercising discretion four points should be considered: (1) the position and interest of any children of the marriage, (2) the possibility of the marriage of the petitioner and the party with whom misconduct had been committed, (3) the prospect of reconciliation of the husband and wife, (4) the interest that the petitioner should be able to marry and live respectably. To these four points Viscount Simon, the lord chancellor, added a fifth in *Blunt v Blunt* (1943, A.C. 517): "namely the interest of the community at large, to be judged by maintaining a true balance between respect for the binding sanctity of marriage and the social considerations which make it contrary to public policy to insist on the maintenance of a union which has utterly broken down." The old rule that a guilty mother was not entitled to access to her children was overcome by the decision of the court of appeal in *B v D* (1924, P. 174). On the other hand one result of equalizing the grounds of divorce was the marked increase in the number of wives' suits in which the charge was based on a solitary incident at a hotel. In March 1925 Lord Macnaghten called a halt to this kind of petition by declaring that he would not grant decrees in cases where the real facts seemed to be cloaked by an artificial procedure.

By the Judicial Proceedings (Regulation of Reports) Act 1936, the reporting of matrimonial cases by newspapers was limited to the names, address and occupations of the parties and witnesses, legal submissions, summonings up and judgments and verdicts of juries. Thus the recommendation of the divorce commission (9) above was dealt with in more drastic fashion than was proposed.

The Matrimonial Causes Act, 1937—This Act was promoted by a private member of parliament, A. P. (later Sir Alan) Herbert, and after discussions in both houses of parliament was finally passed in July 1937 to take effect from Jan. 1, 1938. It was largely based upon the recommendations of the royal commission published in 1932. To adultery as grounds for divorce were added desertion for three years, cruelty, and unsoundness of mind regarded after five years' duration as incurable. No divorce proceedings could be initiated until three years after the date of marriage, but the courts were given power to reduce this period in cases of exceptional hardship or depravity. The act increased the grounds of annulment of marriage, in one case, at least, a post-nuptial matter (wilful refusal to consummate) was made a ground of annulment and not dissolution, this being due to the pressure of those who did not wish to see grounds of divorce further increased. A further feature of the act was that it laid no compulsion whatever upon the church in the matter of remarriage of divorced persons leaving the church free to recognize or not the law of the land. But, as was said in *Weatherley v Weatherley* (1947, A.C. 638) by Lord Jowitt, the lord chancellor: "The marriage which is contemplated in the Book of Common Prayer is a life-long union which imposes an obligation on the one spouse towards the other to love and to cherish till death us do part." The fact is that the law of the land cannot be co-extensive with the law of morals, nor can the civil consequences of marriage be identical with its religious consequences. What marriage means to different persons will depend upon their upbringing, their outlook and their religious belief. Problems as to what are adequate grounds for divorce are to be solved not upon a consideration of the Christian doctrine of marriage as laid down in the Book of Common Prayer, but on the true construction of the relevant Acts of Parliament."

Matrimonial Causes Act, 1950—This act, among other changes, consolidated the law relating to divorce. By section 3

either spouse might get a decree on the grounds of: (1) adultery, (2) desertion without cause for a period of at least three years immediately preceding the presentation of the petition, (3) cruelty, (4) the respondent being incurably of unsound mind and having been continuously under care and treatment for at least five years immediately before the petition. In addition, a wife might petition on the ground that her husband had, since the celebration of the marriage been guilty of rape, sodomy or bestiality. Section 2 forbade presentations of petitions for divorce during the first three years of a marriage except where, in cases of exceptional hardship or exceptional depravity, a judge, after considering the interests of any children of the marriage and the question of reasonable probability of reconciliation, otherwise allowed. A successful petitioner is first granted a decree nisi, once that decree is made absolute and the time for appeal has passed, or the appeal has been dismissed, both the divorced persons may remarry.

Jurisdiction in Divorce Petitions—The act of 1857, which introduced judicial dissolution for the first time, made no specific provision for jurisdiction of the courts of England (and Wales) in divorce suits. For a short time the courts held that they were competent to entertain divorce petitions on the basis of the (British) nationality of the parties. This basis gave way to one in which the residence of the parties was made the decisive factor, this having been the test (by reason of the Statute of Citations, 1534) of jurisdiction in the ecclesiastical courts. But in 1895 it was finally established in *Le Mesurier v Le Mesurier* A.C. 517 (a decision of the judicial committee of the privy council which had been accepted as stating also the law of England), that courts have jurisdiction to entertain divorce proceedings only where both the parties are domiciled in England at the commencement of the proceedings, the place of celebration of the marriage not being relevant for this purpose. The rule of English law being that a wife automatically has the domicile of her husband, much injustice resulted, thus, if an English wife were deserted by her husband who had gone abroad and changed his domicile, she would have to go to the courts of that country for her remedy, always supposing that it was a country which acknowledged divorce. In 1937 and in 1944 certain statutory exceptions to this rule were enacted, but the main exception was first introduced in 1949 and then consolidated in the 1950 act. In the case of proceedings, among other things, for divorce, even though the husband is not domiciled in England the English courts have jurisdiction if the wife is resident in England and has been ordinarily resident there for a period of three years immediately preceding the commencement of the proceedings and the husband is not domiciled in any other part of the United Kingdom or in the Channel Islands or in the Isle of Man. Where the courts take jurisdiction under this new provision, they are ordered to determine the issue in accordance with the law which would be applicable in a normal case, i.e., where both parties are domiciled in England at the time of proceedings. In such a case, it seems, though it has never been decisively determined in the courts, that an English court will apply only the English domestic law of divorce, disregarding the law of the husband's domicile by which divorce might not be permitted.

English courts will only entertain divorce petitions relating to "Christian" marriages. This expression relates not to Christianity as a religion but to the concept of marriage acknowledged and recognized by that religion, so that non-Christians whose concept of marriage in the defined aspects, is identical with that of Christians are entitled to have their marriages recognized and adjudicated upon in English courts. Indeed, as Lord Sumner said, the phrase "Christianity is part of the law of England" is "really not law, it is rhetoric." The "Christian" concept asks only that the marriage should be a "voluntary union for life of one man and one woman, to the exclusion of all others." Thus, both Jewish and Japanese marriages, among others, come within this definition, but polygamous marriages in so far as divorce is in issue, cannot be adjudicated upon in England. The mere fact that a marriage may be terminated by unilateral action of a party would not take that marriage, if it were otherwise within the definition, out of the scope of the "Christian" marriage.

Summary Proceedings for Separation—The legislature

sought to extend the relief afforded by the courts in matrimonial causes by a procedure fairly to be considered within the reach of all classes. In 1895 an act was passed which re-enacted in an improved form the provisions of an act of 1878 of similar effect. By the act of 1895 was given to a married woman whose husband (1) has been guilty of an aggravated assault upon her within the offences against the Person act, 1861, or (2) has been convicted on indictment of an assault on her and sentenced to pay a fine of more than £5 or to imprisonment for more than two months, or (3) has deserted her, or (4) has been guilty of persistent cruelty to her or of wilful neglect to maintain her or her infant children and by such cruelty or neglect shall have caused her to leave and live apart from him, to apply to a court of summary jurisdiction and to obtain an order containing all or any of the following provisions: (1) that the applicant be not forced to cohabit with her husband, (2) that the applicant have the custody of any children under 16 years of age, (3) that the husband pay to her an allowance not exceeding £2 (later £5) a week. (The words in italics above were repealed by the Separation and Maintenance act, 1925, with the result that a wife might apply to the magistrates notwithstanding that she had not left her home because of her husband's neglect and cruelty.) The act provided that no married woman in guilty of adultery should be granted relief, but with the very important condition, altering the rule of the common law, that the husband should not have connived at the adultery or conducted to it by wilful neglect or by misconduct or otherwise. Reforms were made in this branch of the law in 1949 and 1950.

Scotland and Ireland—So far as matrimonial laws are concerned Scotland and Ireland are just as independent of the English law as are foreign countries.

In Scotland marriages may be judicially dissolved for two causes, adultery and wilful desertion, these being the grounds at common law. Wilful desertion for three years was made a statutory ground of divorce in 1938, and two new grounds were added: incurable insanity after care and treatment as an insane person for five years, cruelty, sodomy, and bestiality. Actions for judicial separation also are available. Contumacious, connivance and conduct conducive (the latter pleaded as *inconcivium*) are bars to relief. A petitioner's adultery is no bar to a divorce but may be set up by the accused spouse by way of counterclaim (delay in prosecuting the suit has to be considered by the court but is rarely a bar to relief). The lord advocate has much the same powers as the king's proctor in England in matters of collusion.

In Ireland by article 41 of the constitution of Eire (i.e., of the Republic of Ireland) the family is recognized as "the natural primary and fundamental unit group of Society, and as a moral institution possessing inalienable and imprescriptible rights, antecedent and superior to all positive law." In consequence, the state is pledged to guard with special care the institution of marriage, on which the family is founded, and to protect it against attack. The same article provides that no law shall be enacted providing for the grant of a dissolution of marriage. Further, no person whose marriage has been dissolved under the civil law of any other state, but which is a subsisting valid marriage under the law of the Republic of Ireland, shall be capable of contracting a marriage in Ireland during the lifetime of the other spouse. Thus no divorce may be granted in Ireland, and foreign dissolution decrees will only be recognized where given in the court of the common domicile of the parties. Proceedings for nullity and judicial separation may still be brought in Ireland.

Divorce in Northern Ireland is controlled by a Matrimonial Causes act of 1949. Either party may petition on the grounds of adultery, desertion for three years, cruelty and insanity after five years' care and treatment, and a wife may petition on grounds of rape, sodomy or bestiality.

COMMONWEALTH OF NATIONS

In Canada, though divorce is a matter exclusively within the control of the dominion parliament, that body did not see fit to pass any general overriding act with the result that the divorce laws of the ten provinces which remain in force until altered or

repealed by dominion legislation vary considerably. The provinces of British Columbia, Alberta, Saskatchewan and Manitoba adopted English law after 1857 (1858 for the first named, 1870 for the other three), so that their courts have jurisdiction, as was available in England after the Matrimonial Causes act of that year, to grant decrees of divorce. As to Ontario, by a dominion act of 1940, the English law of divorce as in July 1870 was made to apply therein; the date before the date chosen in this enactment was to make the law of Ontario uniform with that of Manitoba, Saskatchewan and Alberta. In the case of Nova Scotia, New Brunswick and Prince Edward Island, English law was introduced well before 1857, but, by legislation of the provinces themselves (effected before the dominion was established in 1867), the power to grant divorce was given to the respective provincial courts. The courts of Quebec were not given divorce jurisdiction. "Marriage can only be dissolved by the natural death of one of the parties, while both live, it is indissoluble" the law is the same for Newfoundland incorporated as a province of the dominion in 1949. In 1935 the dominion parliament, following the provision of the English act of 1923, enacted that in those provinces possessing divorce jurisdiction a petitioning wife need not prove more than the adultery of her husband.

In Australia the grounds of complete divorce vary according to the state but are generally wider than in England including conduct which would only justify a judicial separation in England.

In New Zealand the grounds of absolute divorce are: (1) adultery, (2) wilful desertion for three years, (3) habitual drunkenness for four years coupled with cruelty or desertion by the husband and neglect of household duties by the wife, (4) conviction and sentence of imprisonment for seven years or more for attempting to commit the murder of the petitioner, or wounding of the petitioner or a child of the parties, (5) conviction for the murder of a child of the parties, (6) incurable lunacy for at least ten years, including confinement for seven of these years, (7) failure to comply with a decree for restitution of conjugal rights, (8) three years of separation agreed either orally or in writing, (9) a three years' lapse of time after the making of a New Zealand decree of judicial separation, (10) rape, sodomy, bestiality. A married woman in New Zealand who, if a *feme sole*, would be domiciled there, may present a divorce petition in New Zealand, regardless of her husband's domicile elsewhere, providing that they have been living apart for at least three years.

In the Union of South Africa the Roman Dutch law is in operation for the most part, the grounds of divorce being: (1) adultery or unnatural offenses, (2) malicious desertion, (3) lifelong imprisonment, (4) five years' imprisonment after declaration that the respondent is a habitual criminal, (5) incurable insanity after seven years.

EUROPE

As regards European countries, there is no complete divorce where the Roman Catholic Church still preserves its ancient powers and influence.

Italy, Spain and Portugal—In Italy a husband may secure a divorce *a mensa et thoro* on the ground of his wife's adultery. The wife is entitled to the same decree if her husband keeps a concubine in such a way as to constitute a grave indignity to his wife, or if he voluntarily deserts her or fails to make a home for her, or is guilty of violence, threats or cruelty endangering her safety or health, or if he is sentenced for a grave crime. The Italian courts do not recognize foreign divorces relating to Italian subjects, but if a national of a foreign country celebrates his marriage in Italy and then gets a decree of divorce in another country, this decree, under certain conditions, may be enforceable in Italy through special proceedings (*deliberazione*) in a court of appeal. In Spain and Portugal the law is practically the same as in Italy.

France—In France the law of divorce has had a chequered history. Before the Revolution the Roman canon law prevailed, marriage was considered indissoluble and only divorce *a mensa et thoro*, known as *la séparation d'habitation*, was permitted, though it would appear that in the earliest age of the monarchy divorce *a vinculo matrimonii* was allowed. But the French Revolution

swept away marriage among the institutions which it overwhelmed, and by the law of Sept. 20, 1792, so great facility was given for divorce a *vinculo matrimonii* is practically to terminate the obligations of marriage. A reaction came with the Code Napoléon, yet even under this system of law divorce was fairly easy. On the restoration of the monarchy in 1816 divorce a *vinculo* was abolished.

Divorce was re-enacted by a law of July 27, 1884, the provisions of which were simplified by laws of 1886 and 1907. But a wide departure was made by these laws from the terms of the Code Napoléon. Divorce by consent was not permitted, and the following became the causes for which divorce was allowed: (1) adultery by either party to the marriage at the suit of the other, without in the case of adultery by the husband the aggravation of introduction of the concubine into the home required by the Code, (2) violence (*exces*) or cruelty (*sauvies*), (3) *injures graves*, acts reflecting on honour or reputation and such things as unjustifiable refusal of marital rights or habitual drunkenness, and (4) *peine afflictive et infamante*, a legal punishment involving corporal confinement and moral degradation.

In addition to its recognition of full divorce, the French law recognizes *séparation de corps*. The grounds are the same as those for divorce, and if a *séparation de corps* has existed for three years, it may be turned into a divorce upon the application of either party to the court.

On a divorce both parties are at liberty to remarry. The husband could remarry at once, but the wife (article 296 of the Code) was only allowed to remarry after an interval of ten months. By the act of 1907 this article was abolished, and the wife allowed to remarry as soon as the judgment or decree granting the divorce had been entered, providing 300 days had elapsed. Under the law of March 26, 1924, article 295 was amended in favour of greater, but not complete, freedom of remarriage of the parties divorced, not still in a state of wedlock. The publication of divorce proceedings in the press is forbidden under heavy penalties. After a divorce the wife may not continue to use the name of her divorced husband. An appeal may be brought against a decree of divorce within two months, and a decree made on appeal is subject to revision by the court of cassation within two months. A decree must be transcribed in the register of civil status before it becomes absolute. (Cf. Woodland v. Woodland, 44 The Times L.R. 495.)

Germany.—In Germany, the absence of a peace treaty after World War II delayed re-establishment of a uniform code. In the British zone of control in western Germany, law no. 16, part 2, *Recht der Ehescheidung*, followed closely the old pattern of German law. Divorce might be decreed for adultery, violation of marriage duties, disreputable or immoral conduct (*Eheverfehlung*), mental derangement, mental diseases which make "spiritual companionship" impossible or infection with contagious and repulsive diseases. Petitions on these grounds had to be "morally justified," especially in relation to the duration of the marriage, the age of the parties and, where relevant, the circumstances, in which the disease was contracted. If the parties had not kept a common household for three years and if there was a "deep rooted, incurable disruption of the marriage bond," again divorce might be granted. In certain circumstances, a woman retained her husband's name after divorce but, unless she gave birth to a child within the ten months after dissolution, she might not marry again within that period (section 8).

Other European Countries.—In Austria the grounds for complete divorce are adultery, conviction for a crime for which the penalty could be five years' imprisonment, malicious desertion, cruelty or conduct endangering life or health, and invincible aversion. A judicial separation is allowed on the same grounds, and also by mutual consent. In Hungary the law is very similar.

Dissolution of marriage by mutual consent is allowed in several European countries. Thus in Belgium this course is permitted, subject to the approval of the court. The other grounds of complete divorce in Belgium are the adultery of the wife, the adultery of the husband only if he has brought a concubine to the home, cruelty and conviction for an infamous offense. The law on separa-

tion was modified by a law of March 20, 1927. There has to be an interval of ten months before remarriage in the case of the wife. Divorce by mutual consent is also permitted subject to proceedings which take a year to complete. In these cases, three years must elapse before either party may remarry. In Switzerland divorce by mutual consent was abolished in 1912, grounds for divorce are adultery, cruelty or dishonourable treatment, wilful desertion for three years and incurable insanity or mental disease of three years' duration, and in cases of gross antagonism a couple may be granted a trial separation for two years, followed by a divorce if there is no reconciliation. The ground most relied on, however, is that of "conjugal disturbances" under article 142 of the code.

In Sweden a divorce is granted after the expiry of a year from the date of a judicial separation allowed on the ground of aversion, if there has been no reconciliation, other grounds of divorce are adultery, six years' absence by one spouse, without news, insanity for three years, conduct endangering life and imprisonment for life. These are judicial grounds, but a divorce may also be pronounced by means of the royal prerogative against a person who has been the subject of a sentence for grave crime, or on proof of violence, inebriety or profligacy. In Norway and Denmark the grounds are very similar and in the former country a royal decree of divorce may be obtained by mutual request after three years of separation. In the Netherlands judicial separation is allowed on the usual grounds of the canon law, and complete divorce can be secured for each of the following grounds: adultery, wilful desertion for five years, unnatural offenses, life imprisonment and absence for ten years. The court sits in camera.

The U.S.S.R.—In Soviet Russia, in place of the previous procedure, under which a divorce was granted by either spouse alone without assuming costs, a decree of 1946 provided for a judicial procedure for divorce. In 1947 a decree prohibited marriages between Soviet citizens and foreigners. Under the imperial law the grounds for divorce used to be adultery, bigamy, impotence at the time of marriage, absence of one spouse without any news for five years, exile to Siberia and loss of civil rights. (Sv. H. C. Mo, J. E. S. S.)

UNITED STATES

In colonial times the only available method of dissolving a marriage was by act of a legislative assembly, and such power was exercised by some state legislatures but later was denied by constitutional provisions in all but a few states. Divorce is to be distinguished (1) from a decree of annulment of marriage, which is a judicial determination that no legal marriage has ever existed, and (2) from a decree of separation, which permits or commands the parties to live apart, but does not completely and for all purposes sever the marriage tie.

Divorce Rate.—Statistics concerning divorce have been gathered by the U.S. department of labour, its bureau of the census and the national office of vital statistics. The latter agency collected data showing that the ratio of divorces to population rose steadily after 1867 with the exception of temporary dips in the general upward curve after wars and business depressions. The 1867 rate was 0.3 divorces per 1,000 population. By 1897 it was 0.5 and by 1907 it had reached 0.9 per 1,000 population, increasing at an accelerated pace to a high in 1946 of 4.1 per 1,000 population, including the armed forces overseas. The total number of divorces granted in 1946 was estimated at 610,000. The rate declined to 3.4 in 1947 and 2.8 in 1948. The divorce boom and decline, following World War II, repeated the post World War I pattern. This phenomenon was attributed to hasty and ill conceived wartime marriages and to unstable conditions during wartime.

The effects of economic conditions are also reflected in the United States divorce rate. When times are good and income seems likely to be assured, the divorce rate rises. In periods of industrial depression it falls, fluctuating thus in the same way as the marriage rate. For instance, the divorce rate dropped during the depression years commencing with 1929, levelled off during 1932-33 and mounted steadily thereafter during the industrial recovery.

Government figures also show interesting variations in the divorce rate between different states and different regions of the United States. The rate in Nevada, for instance, for many years ran from 24 to 35 times that for the nation as a whole, and the Florida rate averaged between 2 and 3 times the national rate. These states, and a few others, attracted "divorce business" through the enactment of laws making quick divorce easily available to persons from other states having less liberal divorce laws. With the exception of Florida the divorce rate was generally lowest in the states along the Atlantic seaboard rising somewhat in the northern Mississippi valley area and climbing still higher in the region to the south and west. But generalizations as to regional trends were subject to such notable exceptions as Wisconsin, the Dakotas, Iowa, Nebraska and Louisiana, where the divorce rates remained generally lower than the national average.

Two statements often made regarding divorce in the United States are not warranted by the statistics, namely (1) that the real motive

of one or both parties to most divorces is the desire for marriage to a third person and (2) that a large proportion of divorces are granted to persons who move from one jurisdiction to another in order to avail themselves of lax divorce laws. On the first point, U.S. statistics are practically silent since, in issuing a marriage license to parties one or both of whom have been previously divorced, no record is ordinarily made of the fact. In Connecticut, however, for a number of years this information was required and, if the statements were trustworthy, the number of persons remarrying each year was about one third of the total number of persons divorcing—probably a rate not widely different from that of widows and widowers of the same age. What statistical evidence there was on the subject therefore tended to discredit this popular opinion.

The evidence against the second belief was even more conclusive. About four fifths of all the divorces granted in the United States were issued to parties who were married in the state in which the decree of divorce was later obtained, and when we deduct from this number one fifth those divorces in which the parties migrated for other reasons than a desire to obtain an easy divorce, the remainder constituted a small, almost a negligible, fraction of the total number.

Legal Aspects.—Divorce became available in every state the District of Columbia the territories the insular possessions and the Canal Zone. The grounds for divorce and the procedures through which it may be obtained are determined by the statutes of each political division. Such statutes are derived principally from ecclesiastical law which expresses certain moral concepts. Thus divorce is granted only upon proof that one spouse, and only one, is guilty of conduct showing moral culpability within one of the categories specified by statute. If both parties are guilty there can be no divorce, and by the same token, if neither party is guilty of misconduct, no divorce can be granted, even though both may desire it. Moreover, husbands and wives must not collude in the commission of a matrimonial offense or the fabrication of evidence of such an offense for the purpose of obtaining a divorce. Nor will a divorce be granted if the wronged party has condoned or forgiven the matrimonial offense.

In actual practice 85% to 90% of divorce suits in the United States are not contested. The grounds alleged are more often a cloak than a clue to the basic cause of marital discord. Thus desertion, which carries little opprobrium, is the ground charged in about one-third of all divorce suits. Physical cruelty is alleged in another third or more of the cases, and in many instances is merely a pretext for a sort of physical aggression even though trivial, as meeting legal requirements. Less than 10% of divorces are granted for adultery, although infidelity is one of the real causes of separation in a majority of instances. Among the grounds for divorce which are specified in various states are habitual drunkenness, nonsupport, conviction of felony, impotency, incurable insanity, communication of venereal disease, habitual indulgence in violent and ungovernable temper and in duties to the person of an innocent spouse rendering his or her condition intolerable.

The great variation in the legal requirements for divorce in the different states stimulated so-called "matrimonial divorces." Residents of states where divorce was hard to obtain sought divorce in other states, such as Nevada, where legal grounds and procedures facilitated the severing of marital ties. At mid-th century only, six weeks' residence was required of an applicant for divorce in Nevada and Idaho. Florida required 90 days' residence and Wyoming only 60 days, except that in the latter state a year's residence was necessary if insanity was the ground for divorce. Residence requirements in other states ran much higher, the majority ranging from six months to a year or more.

Conflicts between state laws created great uncertainty as to the validity and scope of out-of-state divorces. Parties to such divorces were sometimes involved in serious legal difficulties. The United States supreme court ruled that the courts of any state have the right to inquire into the traditional facts in connection with divorces decreed granted by other states before recognizing such decrees as valid. The "full faith and credit clause" of the constitution required the recognition only of those out-of-state divorces where jurisdiction is based upon the actual residence of the plaintiff established in good faith and not merely for the purpose of divorce. It therefore became possible for persons who married after obtaining a divorce in one state to be prosecuted and convicted of bigamy in another state. Other complications arose in connection with the effect of out of state divorces on property rights. The U.S. supreme court has held, in a concept called by one of the justices "divisible divorce," by which a marriage might be dissolved in one state without leaving courts of another state from recognizing property rights arising out of the marriage.

Social Considerations.—The frequency of divorce in the United States has been the subject of endless discussion in books and periodicals with general agreement that marital maladjustments and the breaking up of families have grave social consequences, especially through the weakening of parental controls and the inevitable insecurity felt by the children of divorced couples. Certainly the high rate of delinquency among such children may be fairly ascribed to the disorganization of the family life.

It has often been pointed out, however, that divorce is a symptom

rather than an evil in itself. The courts merely sever the bonds of matrimony. By the time married couples reach the divorce courts their marriage is already on the rocks and can only be saved by a complete emotional reorientation.

The generally accepted view at mid-20th century was that the cure for divorce lies in better preparation for marriage through training young people in an understanding of the responsibilities as well as the rewards of family living. Efforts were begun in many schools and colleges to furnish such advice through courses on family relations. Similarly, premarital clinics and advisory services were established in many cities in the hope of equipping prospective husbands and wives with a sound attitude toward the marital relationship. It was also recognized that efforts to reduce the frequency of divorce should not stop with premarital advice. The same agencies which offer such service are usually also ready to counsel married couples about their difficulties and problems. Conciliation services have likewise been set up in connection with divorce courts. There has no doubt that such efforts had a substantial effect in adjusting marital discord in many families.

Although the most effective action toward reducing the frequency of divorce must be through preparation for marriage and adjustment after marriage, there was general agreement also that divorce laws throughout the United States needed overhauling. There was less agreement, however, as to the type of legal reform that should be enacted. One view was that divorce should be made easier and more elastic. Another view stressed the need to reduce requirements and the grounds for divorce and by providing "cooling off" periods and delays before final decrees could be obtained. Opposing this attitude were the proponents of more liberal divorce laws, contending that the only requirement for divorce should be actual separation of the parties for a period long enough to indicate their intention to live apart permanently. All the old concepts concerning guilt, recrimination, collusion and condonation would be abolished in favour of laws based on an acceptance of divorce as the means by which married couples might lawfully free themselves from a bond that no longer has any emotional validity.

Reformers also advocated the establishment of specialized courts with jurisdiction over all family problems such as settlement of marriage, divorce, alimony, adoptions, bastardy, nonsupport and juvenile delinquency. There was growing sentiment in favour of the passage of uniform divorce laws throughout the United States to put an end to the present confusion between states for divorce litigation and to make it more difficult for runaway husbands to avoid contributing to the support of dependent wives and children. Some progress had been made at mid century toward the latter objective through the enactment by a group of states of reciprocal nonsupport laws providing the means for securing support money in such cases.

BIBLIOGRAPHY.—Publications containing divorce statistics include *A Report on Marriage and Divorce in the United States, 1867 to 1886* published by the U.S. Commissioner of Labor, *Reports on Marriage and Divorce, 1867 to 1906*, *Marriage and Divorce 1916*, *Marriage and Divorce, Annual Reports 1922 to 1932*, *A Review of Marriage and Divorce Statistics, 1887 to 1937*, and the annual *Statistical Abstract of the United States*, all published by the U.S. Bureau of the Census, and the *Statistical Bulletin* published by the Metropolitan Life Insurance Company. Legal aspects of divorce are covered by such text books as W. T. Nelson, *Divorce and Annulment*, 2nd ed. (1945).

(M Dc)

DIWANIYEH, a town of Iraq in 31° 58' N and 45° E about 40 mi below Hilla on the Euphrates, here crossed by a floating bridge, and on the Baghdad Basra railway. The town is a frontier post on the edge of the desert, and is a strategic military point.

DIX, DOROTHEA LYNDIE (1802-1887), U.S. philanthropist was born at Hampden (Me), April 4, 1802. About 1821 she opened a school in Boston. From 1824 to 1830 she wrote books of devotion and stories for children. Her *Conversations on Common Things* (1824) had reached its 60th edition by 1869. In 1841 she became interested in the condition of jails and almshouses, investigating especially the treatment of the pauper insane. Her memorial to the state legislature resulted in improved treatment of the insane, and she thereafter extended her work into many other states and foreign countries. She was superintendent of women nurses during the Civil War, and her labours on behalf of defectives were continued after the war. She died at Trenton, N. J., July 17, 1887.

See Francis Tiffany *Life of Dorothea Lynde Dix* (1892).

DIX, JOHN ADAMS (1798-1879), U.S. soldier and political leader, was born at Boscawen, N.H., on July 24, 1798. He studied at Phillips Exeter academy and at the College of Montreal, and as a boy took part in the War of 1812. In July 1828, having attained the rank of captain, he resigned from the army, and for two years practised law at Cooperstown, N. Y. He soon became prominent as one of the leaders of the Democratic party.

in the state and for many years was a member of the so called "Albany Agency" (q.v.), a group of Democrats who between about 1820 and 1850 exercised a virtual control over their party in New York. In 1833-39 he was secretary of state and superintendent of schools in New York. From 1845 to 1849 he was a United States senator from New York. In May 1860 he became postmaster of New York city, and from January until March 1861 he was secretary of the treasury of the United States, in which capacity he issued (Jan. 29, 1861) to a revenue officer at New Orleans a famous order containing the words, "If any one at attempts to haul down the American flag, shoot him on the spot." He was appointed major general of volunteers in June 1861, and during the Civil War commanded various departments until July 1865. He was minister to France in 1866-69, and in 1872 was elected by the Republicans governor of New York.

His son, MORGAN DIX (1827-1908), was rector of Trinity church, New York city, from 1862 until his death. He published *A History of the Parish of Trinity Church, New York City* (1898-1905) and a biography of his father, *Memoirs of John Adams Dix* (1883).

DIXIE, a popular name given to the southern states of the United States which lie south of the Mason and Dixon line. There are various reasons given for the name, one of the most plausible being that it had its origin in money issued by a bank in New Orleans before the Civil War. On the back of the ten dollar bills was printed the French word *Dix* with other lettering in French, hence the south particularly Louisiana became known as the land of Dixes and thereupon Dixie land. It was about this time that Daniel Emmett, "Negro minstrel" and song writer while looking out on the cold dreary streets of New York city and wishing he were in Dixie, picked up his violin and composed that rollicking song, which has been called the national anthem of the south, "Away down South in Dixie."

DIXON, GEORGE (c. 1755-1800), English navigator. He served under Capt. James Cook in his third expedition, and after his return became a captain in the royal navy. In the autumn of 1785 he sailed in the "Queen Charlotte" in the service of the King George's Sound Company of London to explore the shores of the present British Columbia, with the special object of developing the fur trade. His chief discoveries were those of Queen Charlotte's Islands and Sound (the latter only partial), Port Mulgrave, Norfolk bay and Dixon's Entrance and archipelago. He disposed of his cargo in China and returned in 1788, and published *A Voyage round the World, but more particularly to the North-West Coast of America* (1799), the bulk of which consists of descriptive letters by William Berosford, his supercargo. His own contribution to the work included valuable charts and appendices. He is usually identified with the author of *The Navigator's Assistant* (1791), who was teacher of navigation at Gosport. It is believed that he died c. 1800.

DIXON, HENRY HALL (1822-1870), English sporting writer under the nom de plume "The Druid," was born at Warwick Bridge, Cumberland, and educated at Rugby and at Trinity college, Cambridge, where he graduated in 1846. Three of his novels, *Fort and Paddock* (1856), *Silk and Scarlet* (1859), and *Scott and Strlight* (1862) appeared in the *Sporting Magazine*.

See also Francis Lawley, *Life and Times of "The Druid"* (1895).

DIXON, RICHARD WATSON (1833-1900), English poet and divine, son of James Dixon, a Wesleyan minister, was born on May 4, 1833. At Pembroke college, Oxford, he became one of the "Birmingham group" there who shared with William Morris and Sir Edward Burne-Jones in the pre-Raphaelite movement. He died at Warkworth, of which parish he was vicar, on Jan. 23, 1900. His principal work is *History of the Church of England from the Abolition of the Roman Jurisdiction* (1878-1902). At the time of his death he had completed six volumes, covering the period 1520 to 1570.

Dixon's *Selected Poems* were published in 1909 with a memoir of the author by Robert Bridges.

DIXON, a city of northern Illinois, U.S., on the Rock river and the I. Lincoln highway, 98 mi. W. of Chicago, the county seat of Lee county. It is served by the Chicago and North Western and

the Illinois Central railroads and by bus line.

The population was 11,532 in 1950 and was 10,671 in 1940 by the federal census. Dixon is the centre of a rich farming region, and has a number of manufacturing industries, for which the river supplies power.

It was laid out in 1835 by John Dixon (1784-1876), the first white settler in the county, and was chartered as a city in 1859. In 1832, at the close of the Black Hawk War, Jefferson Davis, Zachary Taylor and Abraham Lincoln were comrades in the old blockhouse that stood near the northern end of the present bridge across the river.

DIZFUL, a town and district in the province of Khuzistan, Iran, in 32° 25' N. and 48° 35' E., anciently known as An damish. It lies 6.50 ft. above sea level on the left bank of the Ab-i-Diz, tributary of the river Karun, here crossed by an imposing bridge 430 yds. in length in large part dating from Sassanian times and recently repaired under British auspices, the central span now being of the suspension type.

The population is estimated at 40,000 and includes Persians, Lurs and Arabs.

Dizful is an important station on the Trans-Iranian railway between Burayrd and Ahwaz.

The town is on conglomerate cliffs about 70 ft. above river level, in which cool and dry underground chambers are extensively cut for use in the hot weather. The ruins of Susa (q.v.) are about 15 mi. to the southwest. The industries peculiar to Dizful are the preparation of indigo, the dyeing of cloths and the making of felts. It is the principal southern market town of the nomad population of Luristan. Indigo was first introduced here in the early 19th century, but has since been almost entirely displaced by imported dyes.

Dizful reed pens are celebrated in the east and extensively exported. In the river bed above the bridge are several flour mills worked by water power. Several canals take off below the bridge and irrigate about 20,000 ac. on either bank, but a far greater area was once served by similar canals and could be again fertilized if the dam, on which the original bridge stood, were reconstructed.

DJAKOVO (DARJOVO), a city of Croatia-Slavonia, Yugoslavia, occupied by Italy in April, 1941, after the axis invasion of the Balkans. Pop. 7,987. Djakovo is a Roman Catholic episcopal see. Bishop Joseph Strossmayer (1815-1905) did much to foster the sense of racial kinship among the Yugoslavs, and the town became a centre of religious and political activity. The cathedral, a basilica with a central dome and two lofty spires, was founded in 1866. Its style is Romanesque, chosen by Strossmayer as symbolical of the position of his country, midway between east and west.

Djakovo has a thriving trade in agricultural produce. Many Roman remains have been discovered.

For a full description of the cathedral, in Serbo-Croatian and French, see the illustrated folio *Stolna Crkva Djakovo*, published by the South Slavonic Academy, 1900.

DJERBA see JERBA.

D LINES, in spectroscopy (q.v.), the pair of lines, characteristic of sodium, in the yellow region of the spectrum. Their separation is too small to be detected with a spectroscope of low resolving power, hence to Joseph von Fraunhofer (q.v.) they appeared as a single line. This line was the fourth prominent absorption line in the sun's spectrum, starting from the red end, and he accordingly designated it by the letter D. It was subsequently resolved into two components D₁ and D₂, corresponding to wave lengths 5895.93 and 5895.97 Å (10⁻⁸ cm.) respectively. An emission line appearing in the chromosphere, D₃ λ 5875.62, has since been discovered. This line is caused by helium.

DLUGOSZ, JAN (JOHANNES LONGINUS) (1415-1480), Polish historian, was the son of the burgrave of Bozeczna. He became the secretary of Bishop (afterward Cardinal) Zbigniew Oleśnicki (1389-1455), and was employed by him on many important missions. In spite of his connection with Oleśnicki he nevertheless supported King Casimir IV in his Prussian policy in opposition to his patron. After the cardinal's death in 1455

he began his *Historia polonica* (13 vol., 1st impression, 1614, 1st complete impression, 1711). This great book, the first and still one of the best historical works on Poland, was based on an exhaustive study of the archives of Poland and Hungary. It was completed in 1479.

Długosz became archbishop of Lemberg in 1478. He died on May 19, 1480, at Piatek.

See Krowczyński, *Critical Considerations of the Polish Works of Długosz* (Cracow, 1874); Michael Bobrzyński and Stanisław Smolka, *Life of Długosz and his Position in Literature* (Cracow, 1893), both of these are in Polish.

DMITRIEV, IVAN IVANOVICH (1760–1837), Russian statesman and poet, was born at his father's estate in the government of Simbirsk on Sept. 20, 1760. In consequence of the revolt of Pugachev the family was compelled to flee to St. Petersburg, and there Ivan entered the army. During the four years from 1810 to 1814 he served as minister of justice under the emperor Alexander. The rest of his life was devoted to literature. He took sides with Karamzin in the battle for a natural Russian language against the Old Slavonic party. His poems include songs, odes, satires, tales, epistles, etc., as well as the fables—partly original and partly translated from Jean de la Fontaine, Jean de Florian and Antoine Arnault—on which his fame chiefly rests.

His writings occupy three volumes in the first five editions. In the 6th (St. Petersburg, 1831) there are only two. His memoirs, to which he devoted the last years of his life, were published at Moscow in 1866.

DMITRIEVSK, a town in the Stalin district of the Ukrainian SSR long 38° 48' E lat 47° 56' N. In 1897 it was a village with a population of 512, but in 1917 its coal mines were developed and metal and chemical industries established. Its population is 51,436.

DNEPROPETROVSK, formerly Ekaterinoslav, a town in a county of the same name, in the Ukrainian SSR. It is situated on the right bank of the Dnieper river above the rapids in 48° 21' N and 35° 4' E, alt. 210 ft. In 1927 under U.S. direction, the construction of a ferroconcrete dam, with sluices and docks allowing ships to pass and turbines for generating electricity was commenced. The proximity of manganese, nitre, coal and iron deposits to the station, and of the Zaporozhny aluminum industry is a great commercial asset. Pressure on the railway system will be relieved by the opening of river transport for wheat, timber, coal, iron and other heavy products. The town has iron smelting, and metal industries employing more than 50,000 men and there are also breweries, flour mills and other smaller industries. In 1895 it became the centre of numerous Franco-Belgian industrial enterprises, and its population has increased from 18,881 in 1861 to 500,662 in 1939. It is a trading centre for the agricultural products of the district. On the site of the present city there formerly stood the Polish castle of Kudak, built in 1635, but it was destroyed by the Cossacks. Grigory Potemkin founded the city in 1786, and Catherine II in 1787 laid the foundation stone of its cathedral, which however, was not built until 1830–35. Paul I changed the name of the city to Novo Rossiysk but its original name was restored in 1802. The oldest part of the city lies very low and is subject to floods. The civic buildings include a mining academy, an archaeological museum and a library.

DNIESTER, one of the most important rivers of Europe (the Borythenes of the Greeks, Danapris of the Romans, Uzi or Uzu of the Turks, Eksi of the Tartars, Elce of Visconti's map [1381], Lerene of Contarini [1437], Luosen of Baptista of Genoa [1514], and Lussem in the same century). It belongs entirely to Russia, and rises in the Smolensk province, in a swampy district (alt. 930 ft.) at the foot of the Valdai hills, not far from the sources of the Volga and the Dvina, in 55° 52' N and 33° 41' E. Its length is 1,400 mi and it drains an area of 202,140 sq mi. In the first part of its course, which may be said to end at Dorogobuzh, it flows through an undulating country of Carboniferous formation, in the second it passes west to Orsha and south through the White Russian SSR to the Ukrainian SSR, where it passes south through the fertile plain of Chernigov and Kiev, and then south east across the rocky steppe to Dnepropetrovsk (Ekaterinoslav).

About 45 mi S of this town it has to force its way across the same granite offshoot of the Carpathian mountains which interrupts the course of the Dniester and the Bug and for a distance of about 25 mi rapid succeeds rapid. The fall of the river in that distance is 155 ft. The Dnieper, having got clear of the rocks, continues southwest through the grassy plains of Kherson and Taurida, and enters the Black sea by a considerable estuary in 46° 30' N and 32° 20' E with the town of Kherson on its right bank. On this ramifying lagoon, into which the Bug also pours its waters, stands Nikolaev. Navigation extends as far up as Dorogobuzh, where the depth is about 12 ft., and rafts are floated down from the higher reaches. The banks are generally high, more particularly the left bank. About the town of Smolensk the breadth is 455 ft., at the confluence of the Pripiet 1,400, and in some parts of the Dnepropetrovsk district more than 14 mi. In the course above the rapids the channel varies very greatly in nature and depth, and it is not infrequently interrupted by shallows. The rapids form a serious obstacle to navigation, it is only for a few weeks when the river is in flood that they are passable, and even then the venture is not without risk and can be undertaken only with the assistance of special pilots. As early as 1732 an attempt was made to improve the channel. A canal, which ultimately proved too small for use, was constructed at Nensitsk in 1780 at private expense, blastings were carried out in 1798 and 1799 at various parts, in 1805 a canal was formed at Kauchitsk and the channel straightened at Sursk, by 1807 a new canal was completed at Nensitsk, in 1833 a passage was cleared through the Staro-Kauchitsk rapid, and in the period 1843 to 1853 numerous ameliorations were effected. The result has been not only to diminish greatly the dangers of the natural channel, but also to furnish a series of artificial canals by which vessels can make their way when the river is low. A ferroconcrete dam was constructed in 1927 across the falls, under U.S. direction, with sluices and docks for letting ships pass, and a station and turbines for the production of electric power. Of the tributaries of the Dnieper the following are navigable—the Bereznia and the Pripiet from the right, and the Sozh and the Desna from the left. By means of the Dnieper Bug (King's) canal, and the Bereznia and Oginski canals, this river has water connection with the Baltic sea.

In the estuary the fisheries give employment to large numbers of people. At Kiev the river is free from ice on an average for 234 days in the year, at Dnepropetrovsk 270 and at Kherson 277.

DNIESTER, a river of southeastern Europe belonging to the basin of the Black sea. It rises on the northern slope of the Carpathian mountains in Poland, and for 150 mi from Zaleszczyki to Karmansy, where it forms a broad estuary as it flows into the Black sea. The Dniester drains an area of 29,670 sq mi. It is excessively meandering, and the current in most parts even during low water is decidedly rapid as compared with Russian rivers generally, the mean rate being calculated at 1½ mi per hour. The average width of the channel is from 500 to 750 ft, but in some places it attains as much as 1,400 ft, the depth is various and changeable. The navigable portion of the river is interrupted by a granitic spur from the Carpathians which gives rise to the Yampol rapids. For ordinary river craft the passage of these rapids is rendered possible, but not free from danger, by a natural channel on the left side, and by a larger and deeper artificial channel on the right, for steamboats they form an insuperable barrier. The river falls into the sea by several arms, passing through a shallow lagoon a few miles southwest of Odessa. There are two periodical floods—the earlier and larger caused by the breaking up of the ice, and occurring in the latter part of February or in March, and the latter caused by the melting of the snows in the Carpathians, and taking place about June. The spring flood raises the level of the water 20 ft., and toward the mouth of the river submerges the gardens and vineyards of the adjacent country. In some years the general state of the water is so low that navigation is possible only for three or four weeks, while in other years it is so high that navigation continues without interruption, but considerable improvements were effected before World War I at government expense. In consequence the traffic increased,

the Dniester used to tip regions of great productivity, especially in cereals and timber. Steamboat traffic was introduced in the lower reaches in 1840. The fisheries of the lower course and of the estuary are of considerable importance, and these together with those of the lakes which are formed by the inundations, furnish a valuable addition to the diet of the people in the shape of carp, pike, tench, salmon, sturgeon and eels.

The tributaries of the Dniester are numerous, but not of individual importance.

DO, in music the first of the sol-fa syllables, or sound names for the notes of the scale; this syllable having been substituted, as being more sonorous, for *Ut*, which was originally the first of these syllables—*ut, re, mi, etc.*—as chosen in the 11th century by Guido d'Arezzo when he devised his system of solmization. Hence in the Tonic Sol-fa system, based on what is called the "movable *do*," *do* is the tonic of whatever key may be employed, whereas in the systems employing the "fixed *do*" it is invariably C.

DOAB, a name applied in India according to its derivation (*do*, two and *ab*, river), to the stretch of country lying between any two rivers as the Bari Doab between the Sutley and the Ravi; the Rechna Doab between the Ravi and the Chenab; the Jech Doab between the Chenab and Jhelum; and the Sind Sugar Doab between the Jhelum and the Indus, but frequently employed, without any distinctive adjunct, as the proper name for the region between the Ganges and its great tributary the Jumna.

DOBBS FERRY, a village of Westchester county, New York on the east bank of the Hudson river, opposite the northern end of the Palisades, 20 mi N of New York city. It is served by the New York Central railroad. Population (1950) 6,246, (1940) 5,883 by the federal census. The Masters school is operated by 17 private girls' school there together with the Children's Village. Electrical appliances are manufactured and there are several publishing concerns. It is a typical commuters' neighbourhood with fine country homes. In 1775 Jeremiah Dobbs a Swede (probably from Delaware) began operating a skiff ferry there, which was kept up by his family for a century. During the Revolution fortifications were erected, and the village was a rendezvous for the British army after the battle of White Plains and for an American division in Jan. 1777. Washington's army encamped near by on July 4, 1781 and started thence for Yorktown the following month. In the Van Brugh Livingston house, on May 6, 1783, George Washington and Gov. De Witt Clinton met Gen. Sir Guy Carleton to negotiate for the evacuation of the posts still held by the British.

The village was incorporated in 1873, as Greenburgh, but the original name was soon resumed.

DOBELL, BERTRAM (1842-1914) English bookseller and man of letters, the discoverer of the poet Thomas Traherne, was born at Bittle, Sussex. In 1860 he set up business as a book-seller on a capital of £10, and in 1887 moved to Charing Cross road, where his shop became famous and his catalogues interesting for their literary gossip. Dobell met James Thomson in 1876, and helped him from that time to his death, in 1895 he edited the *Poetical Works* of his friend, with a memoir. His literary work also included the publication of much useful work on Percy Bysshe Shelley and Charles Lamb.

After his death some volumes of his verse containing some admirable sonnets were issued by his son. But his reputation rests chiefly on the identification of Thomas Traherne (q.v.), whose *Poetical Works* he edited in 1903. He died at Hampstead Dec. 14, 1914.

See S. Bradbury, *Bertram Dobell* (1909).

DOBELL, SYDNEY THOMPSON (1824-1874), English poet and critic was born at Cranbrook, Kent. His father was a wine merchant, his mother a daughter of Samuel Thompson (1766-1817), a London political reformer. The family moved to Cheltenham when Dobell was 12 years old. He was educated privately and never attended either school or university. An acquaintance with James Stansfeld (subsequently 1st Viscount) and with the Birmingham preacher politician, George Dawson (1723-1806), which afterwards led to the foundation of the Society of the Friends of Italy, fed the young enthusiast's ardour for the liberal

ism of the day. Meanwhile, Dobell wrote a number of minor poems, instinct with a passionate desire for political reform. *The Roman* appeared in 1850, under the nom de plume of "Sydney Yendys." His second long poem, *Balder*, appeared in 1854. The three following years were spent in Scotland. Perhaps his closest friend at this time was Alexander Smith, in company with whom he published, in 1855, a number of sonnets on the Crimean War, which were followed by a volume on *England in Time of War*. He died on Aug. 22, 1874.

As a poet Dobell belongs to the "spasmodic school," as it was named by William Aytoun, who parodied its style in *Firmilian*. The epithet, however, was first applied by Thomas Carlyle to Lord Byron. The school includes George Gilfillan, Philip James Bailey, John Styan Bayly (1786-65), Dobell, Alexander Smith, and according to some critics, Gerold Massey. It was characterized by an undercurrent of discontent with the mystery of existence, by a vain effort, unrewarded struggle and sceptical unrest.

The standard edition of his *Poems* (1876) includes a memoir by John Nichol, who also edited a collection of his prose writings under the title *Thoughts on Art, Philosophy and Religion* (1876).

DOBERN, a town of Germany, in the Land of Saxony, on the (Freiberg) Mulde two arms of which embrace the town as an island, 35 mi S.E. of Leipzig by rail, and at the junction of lines to Dresden, Chemnitz, Riesa and Oschatz. Pop. (1939) 25,048. The Nikolai kirche dating in its present form from 1485, a medieval town hall, a former Benedictine nunnery and a monument to Martin Luther are notable. The industries include wool spinning, iron founding, carriage, agricultural implement, and metal printing and stamping work.

DOBERAN, a town and watering place in the Land of Mecklenburg, Germany, lying about 2 mi from the shores of the Baltic and 7 mi W of Rostock by rail. Population 5,570. Besides the ruins of a Cistercian abbey founded by Pribislaus prince of Mecklenburg in 1173 and secularized in 1552, it possesses an Evangelical Gothic church of the 14th century, one of the finest in north Germany; a palace, a theatre, an exchange and a concert hall. Because of its delightful situation amid beech forests and its chalybeate waters, Dobern has become a favourite summer resort. In 1793 Duke Frederick Francis caused the first seaside watering place in Germany to be established on the neighbouring coast, 4 mi distant, at the spot where the Heiligen Damm, a great bank of rocks about 1,000 ft broad and 15 ft high, stretches out into the sea and forms an excellent bathing ground.

DÖBLIN, ALFRED (1878-), was born at Stettin on Aug. 10, 1878. After studying in Berlin and Freiburg, he settled in Berlin as a practising doctor. His principal works are *Der schwarze Vorhang* (written 1902-03, pub. 1919), *Die drei Sprünge des Wang-lin* (a romance of China, 1915), *Wallenstein* (historical novel, 1920), *Berge, Meere und Giganten* (a tale of primitive life, 1924) and *Berlin Alexanderplatz* (1929). In these works he combines an epic force of expression with an extremely vivid narrative style. Less important are *Wladislaw Kampf mit der Dampfturbinen* (1918), *Der deutsche Maskenball* (essays, 1921), *Reise in Polen* (an appreciative travel book, 1926), *Afonas* (poem, 1927), *Das Ich über der Natur* (1927), *Babylonische Wanderung* (1934), *Pardon wird nicht gegeben* (1935, Eng. tr. 1937), *Die deutsche Literatur* (essay, 1938), and *Nocturno* (1944).

DOBRENTZI, GABOR (GABRIEL) (1876-1851), Hungarian philologist and antiquary, was born at Nagyszollos. He completed his studies at the universities of Wittenberg and Leipzig, and became a tutor in Transylvania. In 1820 Dobrentzi settled at Budapest, where he held various official posts, and there he spent the rest of his life. His great work is the *Ancient Monuments of the Magyar Language* (*Régi Magyar Nyelvmélték*, 1838 seq.).

Dobrentzi, one of the organizers of the Hungarian Academy, died near Budapest, on March 28, 1851.

DOBRICI (or BAZARGIC) capital of the department of Cahora Ualeni, Dobruja, Rumania. Population 29,938. Dobrici is the centre of a postal district, and has a large annual fair for cattle, horses and sheep.

The small ports of Balcik and Cavarna are situated about 15 mi away, on the Black sea. The population of the district is very mixed, including Turks, Bulgars, Circassians and Tatars, Gagauz and many gypsies.

DOBROVSKY, JOSEPH (1753-1829), Hungarian philologist, was born of Bohemian parentage at Gjermet, near Raab, Hungary, and studied at Prague. In 1772 he joined the Jesuits at Brunn, but on the dissolution of the order in 1773 returned to Prague to study theology, and became tutor in the family of Count Nostitz. In 1792 he was commissioned by the Bohemian Academy of Sciences to visit Stockholm, Abo, Petersburg and Moscow in search of the manuscripts which had been scattered by the Thirty Years' War, and on his return he accompanied Count Nostitz to Switzerland and Italy. Dobrovsky was the real founder of modern Slavonic studies, and the originator of the revival of Czech as a literary language. His grammar and dictionary provided the basis for modern Czech philology, and modern Czech speech. (See CZECH LANGUAGE AND LITERATURE.)

The following is a list of his more important works, *Fragmentum Pragense evangelii S. Marci, vulgo autographi* (1778), *Scriptores rerum Bohemicarum* (2 vols, 1783), *Geschichte der böhm. Sprache und alter Literatur* (1793), *Die Bildsäulen der slav. Sprache* (1799), *Institutiones linguae slavicae dialecti veteris* (1812), *Entwurf zu einem allgemeinen Etymologikon der slav. Sprachen* (1813), and a critical edition of Jordanes, *De rebus Getis*, for Pertz's *Monumenta Germaniae historica*. See Palacky, *J. Dobrovsky's Leben und gelehrtes Wirken* (1833).

DOBRUJA (DOBORECA), a region of southeast Rumania and northeast Bulgaria, bounded north and west by the Danube, east by the Black sea, and south by Bulgaria. Its area is 23,262 sq km, the population (1937) approximately 900,000. It comprises the four districts of Tulcea, Constantia, Durosthor and Bazarzic. It consists of low mountains, fens and sandy steppes, wet swept and drought ridden, but remarkably fertile when the lack of irrigation is considered. Its main port, Constantia, is Rumania's principal seaport, connected by a pipe line with the Rumanian oil-fields.

HISTORY

The district was known to the Greeks in the 6th century B.C. and included the Greek colonies of Istros, Tomi and Dionysopolis. In the 5th and 4th centuries B.C. invading Scythians subjugated and later submerged the Thracian population, whence the later names of Scythia Minor and Scythia Pontica. The Romans first invaded it 75-72 B.C., definitely subjecting it in A.D. 46. They and their successors the Byzantine emperors Romanized the population and erected walls for its defence, but it was repeatedly overrun by Goths, Alans and Huns.

In A.D. 678 Asparuch, Khan of the Bulgarians, settled with his horde, by permission of the Byzantine empire, near the present Nicolai, but soon repudiated his allegiance and founded the first Bulgarian empire, which included the Dobruja, with its mixed population of Slavs, Bulgars and the remnants of the old Roman colonies. It was recovered for Byzantium in 1018, but in 1186 reverted to the second Bulgarian empire, established by the alliance of Bulgars, Vlachs and Cumans. Magyars, Petchenegs and Cumans had repeatedly ravaged it, the two last named settling there in such numbers that it was known as Petchenege. In the 13th century the Tatars frequently raided it. With the decline of the Bulgarian empire, one Dobrotchitz, a condottiere of Wallachian origin, founded here an independent, or at least semi-autonomous, depote, the name Dobruja derives either from Dobrotchitz or from the Topruch Tatars. In 1390 it passed under the suzerainty of Mircea-Voda, Voivode of Wallachia, but after his several capitulations to the Turks (1391, 1393, finally in 1411) it came under Turkish domination for nearly 500 years. These years brought a further ethnical change, numbers of Turks, Tatars and Circassians being settled in the steppes.

The Treaty of Berlin (July 13, 1878) assigned the Dobruja to Rumania, in compensation for Bessarabia, annexed by Russia. The Treaty of Bucharest (Aug. 20, 1913) advanced the frontier 300 southward, the two districts of Bazarzic and Durosthor being ceded to Rumania by Bulgaria. The Central Powers annexed the

entire province under the Treaty of Bucharest (May 7, 1918), the southern half was ceded immediately to Bulgaria, the northern administered provisionally by the Central Powers in condominium, while Rumania was allowed to retain the port of Constantia (Kustenej) as an outlet to the Black sea. The Treaty of Neuilly (Nov. 27, 1919), restored the 1913 frontier, leaving the entire province to Rumania. The Treaty of Croyova in Sept. 1940, restored southern Dobruja to Bulgaria. The territory ceded was about 7,600 sq km or a third of the whole area (population, 350,000), made up largely of the districts of Durosthor and Bazarzic. This fertile quadrilateral contains the important port of Silistra on the Danube and of Balchik on the Black sea. The territory ceded was occupied by Bulgarian troops on Sept. 20. The Rumanians living in the region were to be exchanged for Bulgarians living in the northern Dobruja. Thus the frontier of 1912 was restored.

(N. L. F., H. K. O.)

DOBŠINA, a small town of central Slovakia in the Triassic limestone "karst" zone of the Carpathians near the Golnits valley. Founded by German miners in the 14th century as a result of the wealth of the surrounding mountains in iron, cobalt, copper and mercury, it is now mainly famous for the existence about 3½ mi N.W. of the town of a cavern containing an icefield, nearly 2 ac in area, with remarkable formations. Pop. (1930) 4,683.

DOBSON, FRANK (1887-), British sculptor, was born in London on Nov. 18, 1887. His early training was under W. Reynolds Stephens, later he obtained a scholarship at Hospital-field, Arbroath, New Brunswick. After study in the City and Guilds schools, London, he worked with the Cornish granite cutters. His works include "The Concertina Man," 1919 (stone), "Two Heads," 1921 (red Mansfield stone), "The Man Child," (Portland stone), "Figure of a Woman," 1924 (white marble), "Susanna" and "Morning," 1925, "Cornucopia," 1927 (Ham Hill stone), "Truth," 1930 (bronze), "Pax," 1935 (Portland stone) and "Source," 1944 (terra cotta). His portraits include "The Earl of Oxford and Asquith," 1921 (bronze), "Osbert Sitwell," 1923 (polished brass), "Lydia Lopokova," 1924 (bronze), "Head of a Young Girl," 1925 (plaster), "L. H. Myers," 1925, "Robert McAlmond," "Robin Sinclair" and "Tallulah Bankhead," 1927. In 1931 he designed and executed a series of panels in gilded faience on the river front of Hays wharf, London, illustrating "The Chain of Distribution." He designed the "Calix Majestatis" or Cup of Memory in silver gilt, which was presented to the crown for the palace of Holyroodhouse, Edinburgh, to commemorate the coronation of George VI and Queen Elizabeth in 1937. Examples of his work are in the Tate gallery, London, and the public art galleries in Manchester, Glasgow and Leeds. He helped found the X group, and was president of the London group (1923-7). He was elected A.R.B.S. 1938, and A.R.A. in 1942. (H. Hb.)

See Roger Fry in *The Burlington Magazine*, vol. 45, p. 171 (1925), Clive Bell in *The Architectural Review*, vol. 59, p. 41 (1926).

DOBSON, HENRY AUSTIN (1840-1921), English poet and man of letters, was born at Plymouth and educated at Beaumans, Coventry, and the Strasbourg gymnasium. In Dec. 1856 he entered the board of trade, and from 1884 to 1901, when he retired, was a principal clerk in the marine department of that office. In 1873 he collected the poems which had appeared in various periodicals in a volume entitled *Vignettes in Rhyme*. In 1875 appeared *The Sign of the Lyre*, which contained "The Ladies of St. James's," "The Old Sedan Chair," "My Books," and the delightful "Fables of Literature and Art." The book has the flavour of the 18th century which Dobson loved so well, and of which he has left exquisite pictures in prose as well as in verse. Dobson led the movement in the late '70s for the introduction of French forms, the ballade, the triolet, and the rondeau, forms which he used in his *Proverbs in Porcelain* (1877). *Vignettes in Rhyme* and *Proverbs in Porcelain*, combined in one volume, were printed in the United States as *Vignettes in Rhyme* (1880), and with some additions as *Old World Idylls* (1883) in England. After 1885 Dobson was engaged principally upon critical and biographical prose. His biographies of *Pindar* (1883), *Bewick* (1884), *Steele* (1886), *Goldsmith* (1888), *Walpole* (1890), *Hogarth* (1897-98), *Samuel Richardson* (1902), and *Fanny Burney* (1903) are studies marked

alike by assiduous research, sympathetic presentation and sound criticism. Dobson always added something, and often a great deal, to our positive knowledge of the subject in question, his work as a critic never being solely aesthetic. *Four Frenchwomen* (1890) the three series of *Eighteenth Century Ignatius* (189–96) and *The Paladin of Philanthropy* (1909) contain unquestionably his most delicate prose work. In 1907 he collected his hitherto unpublished poems in a volume entitled *Carmine Icticia*.

See Alban Dobson, *Alban Dobson: Some Notes* (1938), A. Dobson, *Bibliography of the First Editions* (London, 1925).

DOBSON, WILLIAM (1810–1846), English portrait painter, was born in London and by tradition became Van Dyck's protégé. He succeeded him as sergeant painter to Charles I, whom he attended at Oxford. Of all English painters he came nearest to Van Dyck in handling and in courtly, Cavalier spirit. He also shows Van Dyck's influence doubtless acquired from the Royal collection. Portraits by him are in the National Portrait Gallery and the National Gallery, London, and at Windsor, his best are in country houses.

See C. H. Collins Baker, *Life and the Stuart Portrait Painter* (Boston, 1922); C. H. C. Baker and W. G. Constable, *English Painting of the Seventeenth and Eighteenth Centuries* (New York, London, 1930); O. Millar, *William Dobson* (London, 1951). (C. H. C. B.)

DOBSON FLY, insects, of the family *Corduliidae*, allied to the alder flies (*q.v.*) and inhabiting North and South America, Asia, Australia and Africa. The males are remarkable for their large jaws. Dobson flies are placed in the suborder Megaloptera, order Neuroptera (*q.v.*). The larvae are aquatic.

DOCEŦAE, a name applied to those thinkers in the early Christian Church who held that Christ, during his life, had not a real or natural but only an apparent (*doceŦa* to appear) or phantom body. The name is first used by Theodoret (*Ep.* 82) as a general description and by Hippolytus (*Philosophumena*, vii, 8–11). Clement of Alexandria and others use the name of a distinct sect. It must, however, be regarded as a type of Christology. The origin of the heresy is to be sought in Greek Alexandrine and oriental speculations about the imperfection or rather the essential impurity of matter. Traces of a Jewish Docetism are to be found in Philo, and in the Christian form it is generally supposed to be combated in the Johannine Epistles (I ii 22 iv, v 6–9, II 7) and more formally in the epistles of Ignatius (*Ad Trall.* 9 f., *Id. Smyrn.* 2, 4, *Ad Ephes.* 7, cf. *Polycarp. Ad Phil.* 7). It differed much in its complexion according to the points of view adopted by the different authors. Among the Gnostics and Manichaeans it existed in its most developed type, and in a milder form it is to be found even in the writings of the orthodox teachers.

The more thoroughgoing Docetae assumed the position that Christ was born without any participation of matter, and that all the acts and sufferings of his human life, including the crucifixion, were only apparent. They denied accordingly, the resurrection and the ascent into heaven. To this class belonged Docetism, Saturninus, Cerdo, Marcion and their followers, the Ophites, Manichaeans and others. Marcion, for example, regarded the body of Christ merely as an "umbra" or "phantasma." His denial (because of his abhorrence of the world) that Jesus was born or subjected to human development is in striking contrast with the value which he sets on Christ's death on the cross. The other or milder school of Docetae attributed to Christ an ethereal and heavenly instead of a truly human body. Among these were Valentinus, Bardesanes, Basilides, Tatian and their followers. They varied in their estimation of the share which this body had in the real actions and sufferings of Christ. Docetism springs from the same roots as Gnosticism (*q.v.*).

DOCHMIAC (Gr. *doxym*, "a hand's breadth"), a form of verse, consisting of *dochmi* or pentasyllabic feet (usually *u—u—u*) in English "rèbèl, slàves rèbèl."

DOCK, in botany, the name applied to the plants constituting a section of the genus *Rumex*, family Polygonaceae. They are biennial or perennial herbs with a stout root stock and glabrous linear lanceolate or oblong lanceolate leaves with a rounded, obtuse or hollowed base and a more or less wavy, or crisped margin. The flowers are arranged in more or less crowded whorls, the

whole forming a panicle; they are generally perfect, with six sepals, six stamens and a three-sided ovary bearing three styles with much divided stigmas. The fruit is a triangular nut enveloped in the three enlarged leathery inner sepals, one or all of which bear a tubercle. In the common or broad-leaved dock *Rumex obtusifolius*, the flower stem is erect, branching and 18 in. to 3 ft. high, with large radical leaves, heart shaped at the base and more or less blunt, the other leaves are more pointed and have shorter stalks. The whorls are many flowered, close to the stem and mostly leafless. The flowers appear from June to August. In autumn the whole plant may become a bright red colour. It is a troublesome weed, common by roadsides and in waste places fields and pastures, where it is often accidentally introduced with clover and grass seeds. The great water dock *R. hydrodaphnum*, is a tall growing species. Other British species are *R. crispus*, *R. conglomeratus*, the root of which has been employed in dyeing, *R. sanguineus* (bloody dock, or bloodwort), *R. pulcher* (fiddle dock), with fiddle shaped leaves, *R. maritimus*. The naturalized species, *R. alpinus*, or monk's rhubarb, was early cultivated in Great Britain and was accounted an excellent remedy for ague.

Thirty or more species occur in North America, widely distributed in the United States and Canada about one third of which are naturalized from the old world. The roots of the canigre (*R. hymenosepalus*) native to the southwestern United States and Mexico have been used for tanning.

The flesh, solid part of an animal's tail is also known as "dock" (cf. Icel. *doche*, stumpy tail, Ger. *Docke*, bundle, skein). The verb "to dock," especially in reference to horses and dogs, is used of the shortening of an animal's tail by severing one or more of the vertebrae. The English kennel club (rules, 1927) disqualifies from prize winning dogs whose tails have been docked, with the exception of varieties of terriers, spaniels, etc., and such other breeds as may be determined by the committee.

The prisoners dock a railed in enclosure in which prisoners are placed during trial is apparently derived from Flem. *dock*, pen or hutch. It occurs in 1610 as "bail dock, a room at the Old Bailey left open at the top."

DOCKS. The term "docks" is applied to the berthing spaces for ships and includes two classes: dry docks and wet docks. Dry docks are used for the building and repair of ships out of water. They may be fixed or floating dry docks. Fixed dry docks are commonly known as graving docks. Floating dry docks although of various types, are so classified generally but because of their characteristics require further classification and detail of their structure and functions. Floating dry docks are described later in this article.

Wet docks may be natural or dredged inlets or dredged spaces along shore lines or river banks, usually flanked by wharves or platforms to facilitate loading or discharging cargoes of vessels. Such wharves, if parallel to the shore, are marginal wharves and are generally known as quays. If built into the stream or fairway at right angles or oblique to the shore they are generally known as piers. Wharves, quays and piers are integral and component parts of wet docks. The aggregate of dock structures including all appurtenances such as service, storage and administration buildings, cargo handling machinery and transportation facilities constitute a port and is so designated, as for example the port of Southampton, the port of New York and the port of San Francisco.

Where a large range of tide exists, more than 15 ft., large basins for harbour facilities are usually totally enclosed and provided with gates to maintain a uniform depth of water. The gates are closed when the tide begins to fall, as at Liverpool and Le Havre. Such basins surrounded by dikes, breakwaters, quay walls or bulkheads are referred to as closed docks and are vulnerable in time of war. At river and seacoast ports with less range of tides such as Glasgow, Rouen, New York City and San Francisco, dock gates are not used. There the ocean basins and river basins serve as wet docks and also provide for temporary anchorage of ships awaiting dockage. The tendency is to provide tidal berths wherever the tidal range does not exceed 15 feet. Floating

FIG 1—PROGRESSIVE INCREASE IN LENGTH OF STEAMSHIPS FROM THEIR EARLY USE IN OCEAN TRAVEL TO MID 20TH CENTURY

wharves which rise and fall with the tide have been used successfully passengers and cargo being discharged over movable transfer bridges hinged at a fixed shore quay. The intervening water affords space for barge transport. In tideless seas, such as the Mediterranean, the discharging rivers (e.g., the Rhone and the Tiber) become barred by deltas at their outlets. Ports have often been established on coasts of such seas by open basins protected by breakwaters, as at Marseilles, Genoa and Naples. Frequent dredging is usually needed to keep the channels open. Where excessive silting and accumulation of littoral drift from tributaries occurs, reservoirs are built to conserve the river water for sluicing the obstructions at the harbour mouth, as at the port of Dover, Eng.

The present article is concerned with the comprehensive subject of docks and integrates brief descriptions of wet and dry docks, slipways, basins and their approaches, locks and entrances, quay walls, piers and wharves, caissons, equipment and machinery and cargo handling methods.

Scope of Dock Facilities.—The frequent use of a geographical location as a point of embarkation gives rise to improved conveniences for moorings and handling of passengers and cargoes. The interchange of commerce and persons as traffic increases between such locations requires substantial docks, and the operation of modern docks is possible only through the provision of pertinent facilities such as roads, railways, canals, channels and other means of transportation. The growth of fast air transport for passengers and valuable or perishable goods become so extensive that provisions for seaplane bases and inland airports had to be provided for the landing, take off and transfer of cargoes. The economic direction of these accessory facilities led to the establishment of port administrations to correlate these interrelated functions. As a result, most large ports came to be administered by public boards known as port authorities, charged with the promotion, development and maintenance of not only the interrelated services but, in addition, the approach facilities such as highways, bridges and terminals in the contiguous areas.

History.—The story of docks begins with the earliest knowledge of water transportation of men and materials. Such transportation is implied in the earliest phases of historical research, which, for example, uncovered evidence of bronze made in Egypt about 3500 B.C., the nearest source of its essential element, tin, being in England. The navigators of the island of Crete were credited as being the first to establish sea trade routes to Spain and England from the island ports of Knossos and Mesara about 1600 B.C.

The Phoenicians, who doubtless had gained much of their maritime knowledge from the Cretans, formed the thriving trade centres of Tyre and Sidon about 2700 B.C. and became contemporary traders. The earliest known Egyptian port, a predecessor of the modern port of Alexandria, was a Phoenician trading port. Its ruins have been traced as far back as 3000 B.C. The merchant princes of Tyre and Sidon, through their promotion of the forest products of Lebanon, grew rich by exploiting the wealth of Egypt,

Persia and Syria and became at once the envy and target of the less prosperous Mediterranean traders. By 1500 B.C. their commercial trade had extended to Cadiz. Sp. Their harbour works were built of massive stone blocks bonded together and pinned with iron dowels set in lead. Tyre whose prosperity was unattained by sound economic and defense planning was besieged by Nebuchadnezzar, king of Babylon, in the 6th century B.C. The second city of Tyre and the original city of Sidon were destroyed by Alexander the Great in 332 B.C. The Phoenicians, however, continued to establish harbours in Sicily, Sardinia, Spain and Africa. Of these the harbour of Carthage was most famous for advance in planning with its massive structure and unique radial alignment of quays. Carthage prospered as a commercial port until destroyed by the Romans in 146 B.C., it was revived under Roman and Byzantine rule and finally destroyed by the Arabs in A.D. 698, when it virtually disappeared from history.

After the destruction of Tyre and Sidon in 332 B.C., Alexander the Great founded a city and a port on the ruins of the Cretan port at Pharos between Lake Maroutis and the Mediterranean. It constituted the beginning of the modern port of Alexandria, although little remains of its original structures. He utilized the island of Pharos which was later extended to form a peninsula of the mainland, creating a great harbour northeast and a southern harbour. At the easterly head of the island stood an ancient light house called Pharos of Alexandria which was accepted as one of the seven wonders of the ancient world. It was built by Ptolemy Philadelphus about 200 B.C., inscribed 'King Ptolemy to the gods the saviours, for the benefit of sailors,' and mounted a continuous fire at its top. It was partially destroyed about A.D. 400 and levelled by earthquake in 1375.

The ancient Grecian port of Peiræus (330 B.C.) was a natural harbour and centre of trade for North Africa and the Aegean ports. A communicating wall 25 mi. long and 60 ft. high joined Athens and Peiræus, and the area was fortified against attack. The Colossus of Rhodes, a bronze statue of Apollo, variously reported 100 to 125 ft. high, stood on the island of Rhodes from 280 to 224 B.C. It was recognized as another of the seven wonders of the ancient world, serving as a lighthouse and landmark for travellers by sea and land until destroyed by an earthquake.

The legends of antiquity are replete with evidences of maritime activity. During the reign of King Solomon of Israel, Parian marble cut for the building of the temple in Jerusalem was conveyed to Joppa. Biblical lore and the commentaries of the early Christian era refer to periodic journeys of Joseph of Arimathea, a merchant and artificer in metals, to England in quest of tin. These commercial activities marked the early use of primitive port facilities in the British Isles.

The Roman port of Ostia and the several ports in the Bay of Naples were characterized by massive construction embellished with towers and colonnades of architectural grandeur seldom repeated. The port of Ostia was protected by breakwaters of arched alignment, each section terminating opposite a central

island, leaving entrance and exit ship channels as access to the enclosed harbour. Until about A.D. 500 the art of constructing harbour works and foundations below tidewater consisted of dropping huge stones into the sea to form mounds which when

FIG 2—GENERAL PLAN OF THE PORT OF ANTWERP, BELG. AND INSET OF A TYPICAL CROSS SECTION OF THE QUAY WALLS IN THE BASIN CANAL.

roughly levelled formed a base for the more regular quarried stone. The early moles, breakwaters and quays were founded in that manner. It was not until 250 B.C. when Archimedes expounded his principles of specific gravity and the lever that the more modern developments in harbour structures were attempted. It was reserved for the Romans in the reconstruction and development of harbours to employ solid masonry founded on piles as at Ostia on the Tiber. Prior to that time such stone harbour works as were constructed were of massive quarried blocks bonded or fastened with dowels and the interstices filled with small stones or gravel. The first evidence of hydraulic cement has been noted in the Roman walls or breakwaters. Harbour development remained static for nearly 1,000 years until military needs and the advance of shipbuilding and maritime commerce dictated its progress.

Later Progress in Dock Construction.—Modern progress in dock building had its early beginning in the ports of Europe and the British Isles with the Anglo-Saxon migrations from the continent to Dover, the Norse explorations, the Norman conquest of England and explorations of the western hemisphere by Christopher Columbus, the Cabots, Ferdinand Magellan and others from 1492 well into the 18th century.

Early records mention an artificial channel, called the "Trench," cut from the river Frome into the Avon at Bristol, Eng., in the year 1247. It contained quays and wharves along its banks which became the origin of the modern port of Bristol. From its quays, John Cabot set forth in 1497 on his voyage which resulted in the discovery of Cape Breton Island and Labrador.

An elementary form of dry dock was fashioned at Southampton,

Eng., in 1434. It utilized a narrow bay in which a ship was placed at high tide. As the tide fell, the area was closed by a temporary wall of clay timber and brushwood. Later in 1496 a permanent dry dock with primitive gates caulked with clay was built at Portsmouth. While large enough to take the biggest warship of the time, it was enlarged in 1523 and again in 1656. By the middle of the 17th century, numerous dry docks were in service both in English and continental ports and at important shipping centres throughout the world.

Communication between Dover, the nearest English port to France, and the continent of Europe has been traced back to 300 years before the Roman invasion of Britain. The *Commentaries* of Julius Caesar referred to Dover as the "haven between the hills." Henry VIII, following his departure from Dover to meet the French king in 1520, ordered the building of a long pier to serve as a breakwater to protect the harbour. It was never completed and was not high enough above low water to avoid formation of long sand bars along the harbour front.

Not until the beginning of the 19th century did systematic dock construction and building begin to follow closely the demands of steady shipbuilding and marine transport developments. Heavy stone sea walls and extensive open wharf timber construction founded on wood piles were general in this period and remained so until the development of steel piles and reinforced concrete on a commercial basis about 1900. Along the eastern and western seaboard of the United States, timbermen from Norway, Sweden, Canada, Newfoundland and the forests of Maine and Oregon became dominant in the dock builders' fraternity. After 1910, however, with the use of steel bearing piles, steel sheet piles and reinforced concrete, dock construction experienced an evolution because of the increased depths required for berthing ships. The cellular cofferdam type of quay wall formed of steel sheet cells filled with earth and clay was first utilized at Black Hawk harbour at Buffalo, N.Y., in 1909. Thereafter the principle was variously adopted for pier and wharf construction, notably at New York city municipal pier in the Hudson river in 1917, to provide for construction in the dry.

An extensive cellular quay wall construction was adapted to cargo-handling facilities at Sparrows Point, Md., and at the United States navy general cargo wharf at Guam in 1948. At the ore dock on the Cuyahoga river in the Great Lakes port of Cleveland, O., steel sheet cells 100 ft in depth were employed in natural sandy and clay soils and provided for the loads of ore handling equipment in 1950. At that time, steel sheet pile cells were being adapted increasingly to varied conditions of soils and varied depths of penetration to 120 ft below water. While cellular construction had been found to be most economical for heavy

FIG 3—PLAN OF NORTHERN END OF DOCKS SYSTEM AT LIVERPOOL, ENG.

loading where great depths of soft clay were encountered, skill and experience were required in the operation to avoid poor alignment and excessive driving. Numerous variations of steel and concrete bearing piles found application where variety in soils and bearing conditions were encountered. The increasing

frequency of ship sailings demanded improved embarking facilities at points of origin. As longer voyages required larger and sturdier ships of deeper draught, the provisions for mooring and outfitting had to be improved correspondingly.

Dimensions of Shipping.—In designing new port works, it is essential to look forward to the possible future requirements of shipping. The necessity for such forethought was shown by the progressive increase in size not only of the largest ocean liners but also of cargo carrying ships. The 'City of Rome' launched in 1881, was 560 ft long, 52½ ft beam and had a minimum draught of 27½ ft. The 'Campania' and 'Lucania' of 1893 measured 600 by 65 ft. At the close of the 19th century a cargo vessel of more than 500 ft in length did not exist. The limiting draught of the Suez canal was 27½ ft and the largest merchant ship afloat, excepting those in the Atlantic trade, was 530 by 65 ft and had a 28 ft draught.

The period 1900-14 was marked by unusual advances in world wide shipping. In 1910 the largest merchant ship afloat was the 'Mauretania' of 31 938 gross tons, 762 ft long and 88 ft beam, but excluding transatlantic liners the largest cargo carrying ship did not exceed 13 000 tons. In 1914 merchant ships far exceeding the dimensions of the 'Mauretania' were either afloat or building. Harbour authorities were engaged in increasing facilities to serve shipping of far larger dimensions than any which hitherto had used their navigable waters.

Until 1930 no ship of greater dimensions than the largest of those building in 1914 was laid down. The dimensions of the 'Majestic' (formerly 'Bismarck'), laid down before World War I but not completed until 1921, were 56 551 gross tons, 912½ ft length, 100½ ft beam and maximum draught 38.9 ft. The 'Leviathan' (formerly 'Vaterland') had been loaded to 41 ft draught. The 'Queen Mary', laid down in 1930 and launched in 1934, exceeded 1 000 ft in overall length, as did the 'Normandie', launched in 1933, and the 'Queen Elizabeth'. The latter two slightly exceeded the 'Queen Mary' in tonnage and dimensions, the 'Queen Elizabeth' being of about 84 000 gross tons.

In 1899 the largest general cargo vessel afloat had a gross tonnage of less than 8 000 and was 470 ft in length. By 1928 cargo ships more than 600 ft long and of 18 000 to 20 000 tons gross were in service, by 1939 there were 83 vessels entered in Lloyd's Register whose gross tonnage exceeded 20 000, 446 ships within the range of 10 000-20 000 tons were in regular service. In the period 1948-49 there were in service or building 96 steam turbine or motor driven tankers of dead-weight tonnages ranging from 21 000 to 33 000. Of these 66 tankers were of tonnages greater than 25 000 dead weight tons. The tanker 'Atlantic Seaman', launched at Camden, N.J. in 1950, was 659 ft long, almost as long as the U.S. carrier 'Saipan' (683½ ft), and had a beam of 85 ft and a draught of 34 ft. But by 1954 there were tankers approaching 800 ft in length and some with 102-ft beam. Displacement was up to 58 000 tons. An ore carrier 794 ft long, 116 ft beam and displacement of 75 000 to 80 000 tons was under construction and even larger bulk cargo carriers, to 135-ft beam, were being planned.

The progressive development of steam and motor driven ships which governed the evolution of harbour facilities is shown in Fig. 1. The increase in size of ships was the result of commercial rivalry between ocean passenger steamship lines for supremacy in speed and luxurious travel. The development of ocean air travel after World War II, however, had a tendency to discourage further building of superliners such as the 'Queen Elizabeth' and 'Queen Mary'. The growth in ship dimensions combined with the requirements of handling larger and heavier cargoes and

reducing the unproductive time that a ship remains in port, led to the extensive improvement of all port facilities.

Depth of Water.—The deepening and widening of the Suez canal enabled ships of the largest class to trade with eastern ports. By 1928 it was practicable for ships drawing 33 ft to pass through it, and in 1933 the depth over the entire canal was increased to 42 ft. Further improvements provided a surface width of 500 ft by 1953 and there was no reasonable limitation to the capacity of the canal. Important ports of the far east were developed concurrently. The opening in 1914 of the Panama canal having a navigable depth of 40 ft, also had an important bearing on the development of harbours in the far east and on the Pacific coast of America. Work was begun in 1940 on the construction of a third and larger set of locks in the Panama canal but more urgent demands of World War II for labour and materials forced its suspension in 1942.

In general, whereas in 1900 a navigable depth of 30 ft was considered ample, at least 35 ft was regarded later as essential in harbours of the first class and in special cases including the ports used by transatlantic liners, depths exceeding 40 ft and even up to 45 ft were required. The principal ports of the United States provide channel and berthing depths of 35 to 40 ft at mean low water. The berths in which floating dry docks operate are dredged to 50 ft of depth adjacent to their quay walls.

The cost of constructing port works is in general considered approximately proportional to the ratios of the cubes of the depths of the ships for which they are designed. It is thus obvious that the problem of providing port accommodation for shipping of the largest class is one of considerable importance from the point of view of finance, and may become one of balance between the relative economy of ships of large draught and cargo capacity and the capital cost of port construction.

Sites for Docks.—Low lying land adjoining a tidal river or estuary frequently provides suitable sites for docks. The position being more or less inland is sheltered the low level reduces the excavation required for forming the docks and enables the excavated materials to be utilized in raising the ground at the sides for quays. The river furnishes a sheltered approach channel. Notable instances are the docks at the ports of London, Belfast, Rotterdam, Boston, Philadelphia and Norfolk. Examples of docks partially formed on foreshores reclaimed from estuaries are Hull, Liverpool, Le Havre and New York. In the enlargement of the port of Antwerp a series of enclosed docks extending from Krinsschans on the Scheldt 7 mi. below the city was constructed to the old dock system, cutting off a bend of the river (Fig. 2).

Occasionally when a tidal river has a shallow entrance docks formed on its foreshore adjoining the seacoast are provided with a sheltered entrance directly from the sea as in the Le Havre docks at the outlet of the Seine. Many old ports were first established on sandy coasts where a creek, maintained by the influx and efflux of the tide from low lying spaces near the shore, afforded

some shelter and an outlet to the sea across the beach. Some of these such as Calus, Dunkirk and Ostend, had their access improved by parallel jetties and dredging. Docks have been readily formed in low-lying land separated only by sand dunes from the sea. (See HARBOURS.)

In the Mediterranean open basins have been formed in the sea by establishing quays along the foreshore from which wide, solid jetties, lined with quay walls, are carried into the sea at intervals at right angles to the shore. Such basins are sheltered by outlying breakwaters parallel to the coast and are reached at each end through the openings left between the projecting jetties and the breakwater, as at Marseilles and Trieste and at the extensions at Genoa. In some of these ports additional accommodation has been obtained by constructing wide quays along the inner face of the breakwater (Fig 6). Where however the basins are formed within the partial protection of a bay, as in the old ports of Genoa and Naples, the requisite additional shelter has been provided by converging breakwaters across the opening of the bay, and an entrance to the port is left between the breakwaters.

The two deep arms of the sea at New York, known as the Hudson and East rivers, are so protected by Staten Island and Long Island that it has been necessary only to form open basins by projecting jetties or piers into them at intervals from the west and east shores of Manhattan Island and from the New Jersey and Brooklyn shores, to provide adequate accommodation for Atlantic liners and the seagoing trade of New York. Somewhat similar conditions obtain in many of the great natural harbours in other parts of the world as for instance Sydney and San Francisco. In general, the docks of the Atlantic and Pacific sea ports of the United States are situated in natural harbours. The necessity for the construction of breakwaters, such as those of the Delaware river and Long Beach, Calif. is exceptional.
